In plants, sHsps are most abundantly expressed under various stresses in the cytosol, endoplasmic reticulum, mitochondria, and chloroplasts. The *Arabidopsis* genome encodes for at least 50 proteins that include a crystallin-like domain. While it is not yet clear which among them are stress-related proteins, about two dozen fall into two groups of cytoplasmic and organellar sHsps, respectively. In the chaperone network, small Hsps complement Hsp100 by presenting aggregates to Hsp70 for disaggregation.

sHsps prevent the formation of large aggregates in the first place, and thus ensure optimal interaction with Hsp70.

A remarkable property of the sHsps in vitro, in *Chlamydomonas* chloroplasts and in *Synechocystis*, is their ability to transiently bind membranes during stress and confer membrane stability against thermally or chemically induced hyperfluidity.[8] Thus, sHsps may also provide a mechanism for short-term adaptation of membranes to heat shock.

### Hsp60

Hsp60 belongs to the chaperone subfamily named chaperonins. Its prokaryotic homologue, GroEL, mediates polypeptide folding by a well-described cage-sequestering mechanism. Unlike Hsp70 and Hsp100, it cannot act upon large complexes of misfolded protein and cannot solubilize aggregates. Rather, Hsp60 can assist Hsp70-mediated protein disaggregation by accelerating the final refolding steps.[3] GroEL-like Hsp60 can be found in chloroplasts and mitochondria, but not in other compartments of the plant cell, suggesting that it

primarily contributes to the stress protection of these organelles.\[1\]

**Hsp90**

Hsp90 is a highly conserved ATPase chaperone, very abundant in the cytoplasm of eukaryotic and prokaryotic cells, even under nonstressed conditions. Like many chaperones, Hsp90 can minimize stress-induced protein aggregation and, together with Hsp70 and ATP, assist the correct refolding of stress-induced misfolded proteins. Under nonstress conditions, mammalian Hsp90 acts as the central component of a supercomplex involved in signal transduction via interaction with steroid hormone receptors or protein kinases. Plant cells also contain similar complexes composed of Hsp90, Hsp70, and FKBP-type prolyl-isomerase.\[9\] Hsp90 controls the morphology and development of complex eukaryotes. In Arabidopsis are present four highly homologous cytoplasmic Hsp90 genes (>90%) and one form in each organelle: ER, chloroplasts, and mitochondria (Table 2). Hsp90 is the only chaperone for which there are specific inhibitors (geldanamycin, radicicol) that reveal a central role for Hsp90 in the mechanism of evolution.\[10\]

**CONCLUSION**

We describe here a coherent molecular mechanism by which Hsp chaperones can limit damages and actively repair lesions in proteins of plants subjected to rapid and extreme variations of temperature. sHsps may also limit stress damage in membranes. Because chemically modified unrefoldable proteins may occur as a result of other stresses, such as oxidative stress, chaperones may not always act in refolding, but may serve to recognize misfolded proteins that need to be targeted to proteases for degradation.

**Chaperones Link Stress with Evolution**

The mechanism of evolution implies a balance between accumulation of mutations in a population and their selection by environmental stress. It is thought that protein stabilization by molecular chaperones allows numerous mild mutations to accumulate in unstressed organisms, including plants.\[10\] During prolonged environmental stresses, the housekeeping and mutant-buffering functions of chaperones are affected by their recruitment for aggregate prevention/repair duties. Thus, environmental stresses may reveal large arrays of new alleles and of corresponding phenotypes, some of which may better fit the new, extreme environmental conditions. Hence, alongside providing efficient short-term protection against environmental stresses, molecular chaperones can also mediate the long-term evolutionary adaptation of plants to ever more extreme and challenging terrestrial climates.

INTRODUCTION

Plants differentially activate distinct defense pathways in response to stress. Depending on the type of stress, plants synthesize the signaling molecules jasmonic acid (JA), salicylic acid (SA), or ethylene, which regulate the defense response.

Jasmonates (JAs) are fatty acid derivatives synthesized via the octadecanoid (ODA) pathway. They play pivotal roles in wound and defense responses, and in anther and pollen development. The defense JA pathway comprises several signal transduction events: the perception of the primary stress stimulus and transduction of the signal locally and systemically; the perception of this signal and induction of JA biosynthesis; the perception of JA and expression of responsive genes; and finally, integration of JA signaling with outputs from other signaling pathways.

STRESS-INDUCED JA BIOSYNTHESIS

How stress signals affect JA biosynthesis is largely unknown. In Catharanthus roseus cells, elicitor-induced JA biosynthesis depends on an increase in cytoplasmic Ca²⁺ concentration and protein phosphorylation[2] (Fig. 1). In tobacco, wound-induced JA biosynthesis depends on the mitogen-activated protein kinase WIPK.[1]

More is known about the JA biosynthetic pathway itself.[1] The biosynthesis of JAs, which include the biologically active intermediates in the ODA pathway and derivatives of jasmonic acid, begins in the plastids with phospholipase (PL)-mediated release of ω-linolenic acid (LA) from membrane lipids.[1] LA is then converted by lipoxygenase (LOX), allene oxide synthase (AOS), and allene oxide cyclase (AOC) into the intermediate 12-oxo-phytodienoic acid (OPDA). This compound is converted in the peroxisomes into JA by OPDA reductase 3 (OPR3), and by three rounds of β-oxidation. JA can be methylated in the cytoplasm to its volatile derivative methyl-jasmonate (MeJA) by S-adenosyl-L-methionine: jasmonic acid carboxyl methyltransferase (JMT) (Fig. 2).

Wounding induces the expression of several JA biosynthesis genes. Therefore, one possible mechanism for stress-induced JA biosynthesis is de novo synthesis of biosynthetic enzymes. In addition, the expression of JA biosynthesis genes is induced by JAs themselves, indicating that JA signaling is amplified by a positive feedback mechanism.

Several mutants in Arabidopsis thaliana affected in JA biosynthesis have been isolated.[1] The fad3-2fad7-2fad8 triple mutant, lacking the fatty acid desaturases necessary to synthesize the JA precursor linolenate, contains negligible amounts of LA and JAs. The opr3 mutant (also known as dde1: delayed dehiscence1) lacks the OPDA reductase isoform required for JA biosynthesis, but accumulates OPDA when wounded.

JA SIGNAL TRANSDUCTION

How JAs are perceived by plant cells is unknown. The mechanisms whereby JA signaling triggers gene expression are just starting to be elucidated. A JA- and elicitor-responsive element (JERE) in the promoter of the terpenoid indole alkaloid (TIA) biosynthetic gene Strictosidine synthase (Str) from C. roseus interacts with two transcription factors called Octadecanoid-Responsive Catharanthus AP2/ERF-domain proteins (ORCAs).[3,4] ORCA2 was isolated by yeast one hybrid screening using the JERE as bait[3] and ORCA3 was isolated by a genetic T-DNA activation tagging approach.[2] Both belong to the AP2/ERF family of transcription factors, which are unique to plants and are characterized by the AP2/ERF DNA-binding domain.

Significantly, ORCA gene expression is rapidly induced by (Me)JA. In addition, evidence suggests that JA activates preexisting ORCA transcription factors by inducing a posttranslational modification, for example, phosphorylation.[4] Activated ORCA proteins may autoregulate ORCA gene expression as well as regulating TIA biosynthetic gene expression. Alternatively, JA-induced ORCA gene expression can occur via a transcriptional cascade, including a yet unidentified transcription-activating factor.
TAF, which is activated via posttranslational modification (Fig. 1).

In Arabidopsis, the AP2/ERF-domain transcription factor ETHYLENE RESPONSE FACTOR 1 (ERF1) was shown to be involved in JA signal transduction as well as in ethylene signaling. Constitutive expression of ERF1 leads to increased expression levels of defense-related genes that are synergistically induced by a combination of ethylene and JA (including PDF1.2), and confers resistance to several necrotrophic fungi. Therefore, it appears that Arabidopsis also uses a subset of its 124 AP2/ERF-domain transcription factors (including ERF1) to regulate JA-responsive gene expression.

Several JA-insensitive Arabidopsis mutants have been found by screening for a reduction in the inhibition of root growth caused by MeJA or by the bacterial toxin coronatine, a structural analogue of JA and OPDA. The coronatine-insensitive 1 (coi1) mutant is affected in a gene encoding a protein with 16 leucine-rich repeats and an F-box motif. The COI1 F-box protein associates with Skp1-like proteins (S) and cullin (C) to form SCF COI1 ubiquitin-ligase complexes. F-box proteins are the components of SCF complexes, which recognize substrate proteins and target them for degradation via the ubiquitin-proteasome pathway. Therefore, COI1 seems to recruit one or more repressors of JA responses for degradation.

The JA-insensitive mutant mpk4 was identified by its dwarf phenotype, and is affected in the gene encoding the mitogen-activated protein kinase 4.

**JA RESPONSES**

A key role for JAs in defense of tomato against insect herbivores and microbial pathogens was proposed in 1992 by Farmer and Ryan, who showed that intermediates and end products of the octadecanoid pathway (but not other closely related lipids) induce proteinase inhibitors that deter insect feeding. JA is the physiological signal for several wound- and pathogen-induced responses in plants, and it is essential for pollen development in Arabidopsis. Exogenously applied (Me)JA results in major reprogramming of gene expression, including defense-related genes that are activated by wounding and path attack. The JA-responsive

![Fig. 1](image1.png)

Fig. 1 Model for elicitor signal transduction leading to TIA biosynthetic gene expression in C. roseus.

![Fig. 2](image2.png)

Fig. 2 Schematic representation of the JA biosynthetic pathway. A mutant blocked in a biosynthesis step is in italics.
PDF1.2 and THI2.1 genes encode antimicrobial plant defensin and thionin proteins, respectively. JAs also induce the expression of biosynthesis genes leading to the accumulation of antimicrobial secondary metabolites, including alkaloids, terpenoids, flavonoids, anthraquinones, and glucosinolates in different plant species.

Arabidopsis mutants defective in JA biosynthesis or perception are deficient in certain defense responses and are male-sterile. The coi1 mutant is defective in its resistance to insects and certain pathogens, and fails to express JA-regulated genes, including PDF1.2 and THI2.1. A single amino acid substitution in COI1, which disrupts SCF-COI1 complex formation, results in loss of the JA response. The mpk4 mutant is blocked in the induction of JA-inducible PDF1.2 and THI2.1 genes and has reduced fertility. The opr3 mutant shows enhanced sensitivity to the fungus Pythium irregulare and the dipteran insect Bradysia impatiens. The opr3 mutant is male-sterile, indicating that pollen development uniquely requires JA and not OPDA. Fertility is restored in the opr3 mutant and the fad triple mutant by application of JA. OPDA plays a major role as a stress signal, because its synthesis in the opr3 mutant is sufficient to trigger a defense response against B. impatiens and the fungus Alternaria brassicicola.

JAs play an important role in ISR, a form of induced systemic resistance elicited by nonpathogenic strains of the root-colonizing bacterium Pseudomonas fluorescens. The JA signaling pathway interacts cooperatively and antagonistically with the ethylene and SA pathways in a variety of responses, leading to fine-tuning of the complex defense response. Together with JA, ethylene plays a crucial role in defense against necrotrophic microbes, in expression of PDF1.2 and other defense genes, and in ISR. Mutants affected in ethylene signal transduction (including the ethylene receptor mutant ethylene-resistant1 (etr1) and the ethylene-insensitive2 (ein2) mutant) also have reduced expression of certain JA-responsive genes, which are more susceptible to certain microbial pathogens, and cannot mount ISR. A subset of AP2/ERF-domain transcription factors (including Arabidopsis ERF1) may serve as the platform to integrate the input from the JA and ethylene signaling pathways.

Systemic acquired resistance (SAR) is a defense response in which, in contrast to ISR, SA is the key regulatory signal. Transgenic Arabidopsis NahG plants expressing the bacterial SA-degrading enzyme salicylate hydroxylase cannot mount SAR. SAR provides protection in uninfected plant parts against pathogens and is correlated with the expression of pathogenesis-related (PR) proteins with antimicrobial activity. The NPR1 (Nonexpressor of PR genes 1) protein has a dual role in systemic resistance mechanisms mediated by either SA (SAR) or JA and ethylene (ISR). The mpk4 mutant, blocked in JA signaling, exhibits elevated levels of SA and constitutive SAR.

CONCLUSION

The role of JAs in development, defense responses, and gene expression is currently being delineated through the analysis of additional gain-of-function and loss-of-function Arabidopsis mutants, and through the analysis of JA-responsive promoters and transcription factors. Future work will focus on the regulation of JA synthesis, the identification of JA receptors, the identification of JA-responsive transcription factors in different plant species and of other signal transduction steps that regulate transcription factor activity, and on the mechanisms of cross talk between different defense signaling pathways.

Plant Response to Stress: Source-Sink Regulation by Stress

Thomas Roitsch
Universität Würzburg, Würzburg, Germany

INTRODUCTION

Plants are challenged by a variety of biotic and abiotic stress factors. Due to their sessile form of life, higher plants have evolved an enormous metabolic flexibility to cope with adverse stimuli by substantial changes in primary and secondary metabolism. One key target of plant metabolism is the partitioning of assimilates between the autotrophic source tissues and the heterotrophic sink tissues. This results in profound effects on many aspects of growth and development, thereby also affecting crop yield. This article reviews the current knowledge of the underlying regulatory mechanism and discusses possible agricultural and biotechnological implications.

CARBOHYDRATE PARTITIONING IN HIGHER PLANTS

Higher plants are physiological mosaics of source tissues. Their mature leaves, e.g., export carbohydrates to photosynthetically less active or inactive sink tissues such as roots, fruits, and tubers, characterized by net import of sugars. The supply of the transport sugar sucrose is a limiting step for the metabolism and growth of sink tissues. By generating a sucrose gradient to support the unloading of sucrose from phloem, the sucrose-cleaving enzymes invertase and sucrose-synthase are important determinants of sink capacity. Thus they are critical links between photosynthate production in source leaves and growth capacity of sink organs. Carbohydrate partitioning between source and sink tissues—competing for a common pool of carbohydrates—is a highly dynamic process that accompanies all stages of the growth and development of higher plants and is influenced by environmental stimuli.

EFFECT OF PATHOGENS ON SOURCE-SINK RELATIONS

Plants may be challenged by a variety of biotic stress factors such as pests and pathogens that result in substantial harvest losses. Fungi and bacteria may act as biotrophic symbionts that utilize carbohydrates synthesized by the host plant. Fungi in particular have evolved sophisticated structures and mechanisms to create an additional strong sink that drains assimilates from the infected plant. In contrast, necrotrophic pathogens (which may include fungi, bacteria, and viruses) grow on the biomass of the infected plant and ultimately result in the death of the host organism.

Activation of defense responses upon pathogen infection is usually accompanied by a fast induction of sink metabolism, possibly to satisfy the increased demand for carbohydrates as an energy source to activate the cascade of direct defense responses and further mediate physiological adaptations (Fig. 1). The source metabolism is generally inversely regulated. Two mechanisms may account for the observed suppression of photosynthesis in response to pathogens: 1) the direct effect of the pathogen on the expression of photosynthetic genes; and 2) the indirect effect due to induction of sink metabolism mediated via sugar repression of photosynthetic genes (Fig. 1). In addition to the localized source-sink transition, the pathogen infection will also affect whole plant carbon partitioning by creating a new sink that competes with other sinks for the common pool of carbohydrates. During the initial defense response, transient effects on source-sink relations are observed. In addition, biotrophic pathogens will establish persistent changes in assimilate allocations by the permanent establishment of a new sink. The pathogen-induced modulation of the carbohydrate status will also affect the susceptibility of the plant, which is evident from the phenomenon of high sugar resistance, the finding that various key pathogenesis-related genes are sugar inducible, and the finding that overexpression of a yeast invertase in the plant apoplast results in increased resistance to virus infection. The effects of a systemic viral infection on photosynthesis, carbohydrate accumulation, and assimilate partitioning seem to be mediated by the viral movement proteins.

REGULATION OF SOURCE-SINK RELATIONS BY ABIOTIC STRESS

Plants are exposed to a wide range of different abiotic stimuli including irradiance, ozone, temperature, osmotic...
factors, wind, water deficiency and mechanical wounding. Drought and salinity are the two major abiotic stresses that limit plant productivity. Although these two stresses are clearly different in their physical nature, they activate some common reactions in plants.[2] A high root:shoot ratio is an important adaptive response to drought and salinity that, by alleviating stress, permits the plant to recover functional equilibrium.[8] This dry matter redistribution is closely associated with carbohydrate allocation to the roots. Therefore, modulation of the processes involved in carbon metabolism and energy production seems to be a promising approach to the engineering of plants with greater adaptability to water and saline stress.

The photoassimilates produced under salt stress are used to support crucial, mutual processes such as growth and osmotic adjustment. The competition of sink organs for the limited carbon supplies under salinity significantly affects overall plant growth, dry matter distribution, and crop yield. As a consequence, the different growth responses to salinity can be interpreted as resulting from changes in the allocation and partitioning of photoassimilates. In general, salinity causes a reduction in sink enzyme activities, leading to an increase in sucrose in source leaves and a decrease in photosynthesis rate by feedback inhibition. Extracellular invertase activity seems to be particularly involved in salt stress response: The enzyme activity correlates with the redistribution of dry matter and is much higher in the roots of salt-tolerant species. An increase in extracellular invertase activity in transgenic plants improves salt tolerance.[2]

Water deficits in plants lead to physiological modifications such as photosynthesis reduction and osmolyte biosynthesis.[9] Large alterations in source-sink relations with source limitations are induced that result in decreased export of assimilates and decreased crop load. It has been shown that an effect of water stress on phloem unloading (via a decline in invertase activity) correlates with male sterility in cereals and blocks pollination and early kernel development in maize.[7]

**INTERACTIONS AND SIGNAL INTEGRATION**

Under natural conditions plants are simultaneously affected by a variety of both biotic and abiotic stress-related stimuli. Although this fact is neglected when the effect of a single stress is analysed (as is usual), a few studies indicate that naturally occurring multistress situations will differentially affect source-sink relations. For example, it has been shown that elevated levels of CO₂ modulate the effect of powdery mildew infection on carbon partitioning in barley and ameliorate ozone effects on biomass and leaf area.[7]

It is becoming evident that complex regulatory networks operate in plants that link endogenous and exogenous stimuli.[10] The finding that specific subsets of mitogen-activated protein (MAP) kinases are activated in response to different stimuli could provide a molecular mechanism suggesting how diverse signals may be integrated to result in the observed coordinated

---

**Fig. 1** Model for the inverse regulation of sink metabolism/defense responses and photosynthesis by stress-related stimuli. Abiotic and biotic stress-related stimuli activate different signal transduction pathways that are ultimately integrated to coordinately regulate gene expression. Activation of different subsets of MAP-kinases provides a mechanism to integrate different signals, and results in coordinated and signal-specific gene regulation. Any signal that upregulates extracellular invertase will be amplified and maintained via the sugar-induced expression of this enzyme as outlined in Roitsch et al. (From Ref. 4.)
responses, while simultaneously maintaining the possibility for unique signal-specific downstream effects (Fig. 1; Refs. 11,12).

EXTRACELLULAR INVERTASE: KEY METABOLIC ENZYME AND MODULATOR OF STRESS RESPONSES

Supplying carbohydrates to sink tissues via an apoplastic pathway involves the release of the transport sugar sucrose into the apoplast by a sucrose transporter, cleavage of the disaccharide by an extracellular invertase, and uptake of the hexose monomers by monosaccharide transporters. Experimental data demonstrate not only that the extracellular invertase is crucial in supplying carbohydrates to symplastically isolated sink tissues and actively growing tissues, but that this sucrose-cleaving enzyme also plays a crucial role in mediating stress responses. As outlined by Roitsch et al., the function of extracellular invertase in stress responses includes the regulation of source-sink transition and the integration of signals that regulate source-sink relations and defense responses. In addition, the sugar inducible expression of extracellular invertase and defense-related genes provides a feed-forward mechanism for maintaining or amplifying the effect of stress-related stimuli: Upregulation of extracellular invertase by any stimulus enhances sink strength and thus results in an elevated sugar concentration. This metabolic signal further induces extracellular invertase for signal amplification and also results in induction of defense-related genes as depicted in Fig. 1.

CONCLUSION

Evidence is accumulating that both biotic and abiotic stress-related stimuli are important exogenous factors that affect source-sink relations (Fig. 1). This interaction modulates plant growth and development and harvest yield, and thus has profound effects on many aspects of the plant life cycle, and also interferes with productivity in agriculture.

Determination of photosynthetic parameters by in vivo fluorescence imaging could be a valuable noninvasive technique to detect effects of pathogen infection on source-sink relations at early stages, for practical applications and to elucidate the underlying regulatory mechanisms in planta. It will be important to further study the effect of the naturally occurring interactions of various signals to determine possible additive, synergistic and compensating effects between stress-related stimuli and endogenous factors on source-sink relations.

Only scattered information is available about the intracellular transduction of stress-related signals and molecular and cellular mechanisms that contribute to the physiological responses. Numerous attempts in many laboratories to modify carbon fluxes by modifying individual enzymatic steps have been essentially unsuccessful. The challenge remains therefore to unravel the underlying sophisticated network of highly flexible regulatory circuits (with complex interactions and crosstalk) for insight into source-sink regulation at the molecular level. This will allow the predictable genetic engineering of resistant plants by manipulating signal transduction pathways to increase the partitioning of fixed carbon into harvestable sinks despite the ubiquitous presence of biotic and abiotic stresses.

ACKNOWLEDGMENTS

Due to space limitations, the author apologizes for not being able to cite the many important original publications that have contributed to rapid progress in the field of plant response to stress. The great effort of all past and current co-workers, stimulating discussions in weekly Laborseminars, and helpful comments on the manuscript by M. Hofmann and S. Berger are gratefully acknowledged.

INTRODUCTION

Plant-parasitic nematodes are cosmopolitan pests that have evolved various feeding strategies to obtain nutrients from their host plants. These nematodes possess a stylet capable of penetrating plant cell walls and are all obligate biotrophs, that is, they need to feed on living cytoplasm. Some nematodes do this by just withdrawing the plant cell contents, usually causing cell death, after which they move to another cell. In contrast to this “hit-and-run” strategy, other types of nematodes carefully puncture selected plant cells and transform them into elaborate feeding cells. According to their lifestyle, nematodes are considered migratory or sedentary, and endo- or ectoparasites. Most research to date has been focused on root-parasitic nematodes. Here, we will focus on the sedentary endoparasitic species from the family Heteroderidae: the cyst nematodes (Globodera and Heterodera) and the root-knot nematodes (Meloidogyne). The infective stage is the motile second-stage juvenile that penetrates the plant root, usually close to the tip, and moves to the vascular cylinder. Upon initiation of feeding, the nematode loses motility and becomes sedentary. These are the most damaging plant-parasitic nematodes, and they evoke complicated cellular responses in the infected roots.

SYMPTOMS OF NEMATODE-INFECTED PLANTS

Root-parasitic nematodes are called hidden enemies because the above-ground symptoms are not often visible before major damage has been done. Endoparasitic nematodes either destroy root tissues (migratory species) or distort the vascular tissue (sedentary species). In addition, heavily infected plants usually have a less developed root system than normal. An obvious effect of deficient water transport is wilting of the plants in dry weather conditions. Heavily infected plants are stunted and exhibit symptoms of nutritional deficiencies. Lower infection levels often stay undetected because the resulting symptoms are more subtle: lower yields due to a decreased water transport, a reduction in photosynthesis, and nutrient removal by the nematodes.

Although plant-parasitic nematodes are microscopically small and usually inside the roots, their effects can often be seen on the outside (Fig. 1). Root-knot nematodes are named after the characteristic root knots or galls they induce on susceptible plants. In severe cases, the roots become stunted and completely deformed. Mature cyst nematode females transform into cysts that protect hundreds of eggs against adverse environmental conditions. Depending on the species, these cysts are visible as golden to brown globular or lemon-shaped structures loosely attached to the root. The induction of additional lateral roots is another typical symptom seen after infection with certain nematodes (such as Heterodera avenae, H. schachtii, Meloidogyne hapla), which gives a bearded appearance to taproots.

WOUND AND DEFENSE RESPONSES OF INFECTED PLANTS

Nematode infection always causes wounding of plant tissues, especially during the migration step. In the case of migratory nematodes, this leads to massive necrosis throughout the infection process. Root-knot nematodes circumvent strong plant responses during migration because they move between the cells by separating them at the middle lamella. The juveniles usually move down in the cortex to the root tip, where they turn 180° to migrate up in the vascular cylinder. At this point, the root meristem can be severely damaged if several juveniles pass through the same tip and try to find their way up. Cyst nematodes take a shorter route to the vascular tissue: they go straight through the cells toward the center of the root, causing strong necrosis from their point of entry to the place where they settle down.

Plants are usually able to recognize and react to these parasites by switching on defense responses. When the response is too weak or too late, a successful infection (compatible interaction) will result. A rapid and strong defense response (e.g., due to the presence of a resistance gene) will result in a resistant (incompatible) interaction. An incompatible interaction is often characterized by a hypersensitive reaction (cell death and necrosis), that impedes induction of feeding cells or further migration of the nematode.
Changes in gene expression correlated with wound or defense response have been studied in several plant–nematode interactions. For example, the wound-inducible wun1 promoter was rapidly induced by cyst nematodes in potato but only weakly responded to root-knot nematode infection. Induction of pathogenesis-related proteins has been detected in leaves and roots of potato plants infected with different pathotypes of *Globodera pallida*. Analysis of tomato roots 12 hours after infection with root-knot nematodes identified several defense genes to be upregulated. Most of these were induced in the compatible as well as in the incompatible interaction, although with differences in levels and timing. Examples of activated defense genes include peroxidase, chitinase, lipoxygenase, extensin, and proteinase inhibitors. Induced defenses against nematodes are not limited to upregulation of defense proteins; they also include pathways resulting in phytoalexin biosynthesis (such as glyceollin in soybean) and deposition of callose or lignin as a physical barrier.

**DEVELOPMENT OF LARGE FEEDING CELLS IN RESPONSE TO SEDENTARY NEMATODES**

Nematodes that feed for a prolonged period from the same cell(s) induce cytological modifications to increase...
Criconemella xenoplax is a sedentary ectoparasite that feeds for up to eight days from a single cortical cell. The nematode uses its stylet to withdraw nutrients from this cell via a zone of modified cytoplasm. Plasmodesmata between the food cell and surrounding cells are modified in a special way to facilitate solute transport. The ectoparasites Xiphinema index and X. diversicaudatum feed on root tips and transform them into terminal galls. The galls contain enlarged multinucleate cells that arise from repeated mitosis without cell division. The best studied and most pronounced cellular modifications are induced by the sedentary endoparasitic nematodes (Fig. 2). The successful induction of an elaborate feeding site is essential for the survival of these nematodes, because once they become sedentary they are unable to move to another cell. Probably in response to salivary secretions from the nematode, alterations of the nuclei, the cytoplasm, and the cell walls turn normal root cells into huge multinucleate feeding cells. A syncytium (induced by cyst nematodes) is formed by the breakdown of plant cell walls and subsequent fusion of neighbouring cells.

Giant cells (induced by root-knot nematodes) are formed as the result of repeated nuclear divisions without cell division.

NUCLEAR AND CYTOPLASMIC CHANGES IN FEEDING CELLS

Aberrant cell cycles that lead to a higher DNA content are typical for plant tissues that have a nutritional function, such as endosperm and tapetum. This phenomenon also occurs in developing feeding cells, although under a different form in giant cells and syncytia. The first sign of giant cell development is the formation of binucleate cells. Cell plate vesicles initially line up between the two daughter nuclei but then disperse, resulting in the abortion of the new cell plate. Additional mitoses uncoupled from cell division result in multinucleate large cells. The mean number of nuclei per mature giant cell is between 30 and 60 in most studied plant hosts, and the nuclei are also larger than normal. In sharp contrast to

the metabolic and transport capacities of that cell.\[1\]
giant cells, no mitosis has been seen in syncytia induced by cyst nematodes. The enlargement of nuclei indicates that DNA synthesis (uncoupled from mitosis) is taking place within the syncytial tissue during and after the incorporation of new cells through cell wall dissolution.\(^7\) Both types of feeding cells thus contain many large nuclei, and since the transcriptional and translational activity increases at each doubling of the DNA, these cells are functionally equivalent to hundreds of diploid cells. The resulting high metabolism is reflected in a dense granular cytoplasm with many mitochondria, an increase in rough endoplasmic reticulum, and small vacuoles.

**CELL WALL REMODELING IN FEEDING CELLS**

When a cyst nematode selects an initial syncytial cell, the plant cell responds by gradually widening some plasmodesmata to neighbouring cells.\(^2\) The protoplasts of adjacent cells then fuse through the developing wall openings. At later stages, cell wall openings are formed de novo and the syncytium continues to grow by integrating neighboring cells. Giant cell and syncytium cell walls adjacent to the xylem increase their thickness by fingerlike cell wall invaginations that are followed by the plasma membrane.\(^7\) These invaginations enlarge the surface for water transport from the xylem into the feeding cell.

**GENES EXPRESSED IN FEEDING CELLS**

Various strategies have been used to identify plant genes that are upregulated in feeding cells and could thus be important in feeding-cell development or functioning\(^8\) (Fig. 3). Many different plant genes have been found to be activated in feeding cells; the challenge now is to elucidate the role and the importance of these genes in the infection process. Examples include genes for metabolic enzymes, cell wall-modifying enzymes, a water channel protein, cytoskeleton proteins, and genes that are putatively involved in early feeding-cell development, such as cell cycle genes and transcription factors.\(^9\) With the ongoing application of genomics tools to the study of plant–nematode interactions, the number of known plant genes involved in plant–nematode interactions will increase dramatically.

---

**Fig. 3** Gene expression in nematode feeding sites. Promoter trapping is based on the random integration of a promoterless-glucuronidase (gus) gene in the DNA of a plant species, often Arabidopsis thaliana.\(^10\) When inserted downstream from a plant promoter that is inducible by nematode infection, a higher GUS activity (blue color) can be seen at the infection site. The elegance of this method lies in the ability to directly visualize induced expression in nematode feeding sites at various stages of the interaction, while analyzing the specificity of expression using uninfected parts of the same plant and control plants. A. GUS-assay on A. thaliana plant tagged with a promoterless gus-construct. The analysis was performed 3 days after inoculation with Meloidogyne incognita. Galls turn blue because of local promoter activity. B. Detail of a gall, the nematode has been counterstained with acid fuchsine. (Photo courtesy of Mansour Karimi.) INTRODUCTION

Ultraviolet-B radiation (UV-B: 280–320 nm) is highly energetic and can cause damage to a wide range of cellular components, such as DNA, amino acids, and lipids. Plants, because of their sessile nature, are potentially very susceptible to UV-B exposure, and the increase in UV-B as a result of ozone depletion could have severe consequences. Over the last few decades there has been a substantial amount of research on the effects of UV-B on plants.\[1,2\] These studies show a large number of responses including changes in growth and development, increase in protective pigment biosynthesis, effects on photosynthesis, DNA damage, etc. These responses are also very variable, both between species and even within varieties of the same species. Most of these studies, however, have been carried out in controlled environment cabinets. Unfortunately, while providing experimental control, this approach does not provide a realistic comparison to the natural environment and consequently over-states the damaging influence of UV-B. Despite this disadvantage, controlled environment cabinets have provided valuable insight into the cellular changes induced by UV-B exposure, e.g., changes in gene expression. Recently more environmentally significant data is being generated on UV-B stress and a complex picture is emerging of multiple impacts at the physiological and ecological level.\[2,3\] This short review will focus on changes at the molecular level as a result of UV-B–induced stress.\[1,4\]

MOLECULAR RESPONSE TO UV-B STRESS

Gene Activation

It is now apparent that many of the UV-B induced responses require gene activation. Initial studies showed that genes that were required for protection against UV-B were activated, while those for photosynthesis, primary metabolism, etc., were down-regulated. To change gene expression, UV-B, unlike other wavelengths of light, can be absorbed directly by DNA and nonspecifically inhibit DNA transcription. Alternatively, UV-B could be perceived by a specific photoreceptor or in some nonspecific manner (e.g., increased oxidative stress) that subsequently leads to gene regulation. Although no UV-B photoreceptor has been identified, there is some limited evidence that UV-B perception may operate through such a mechanism.\[5\] After perception of the UV-B radiation, a signal transduction pathway(s) must be initiated that eventually changes gene activity. Recent studies on UV-B–induced gene activation have unveiled a complex response involving numerous signal transduction pathways.\[4,6\] These responses are similar in some ways to other stress responses, e.g., to pathogens,\[7\] but differ in various details such as the chemical components of the transduction pathway. At present, a number of characteristics of UV-B–induced signal transduction pathways have been described, with a variety of different components, which include ROS (reactive oxygen species), jasmonate, salicylate, and ethylene (Fig. 1). ROS is generated through a variety of mechanisms, including NADPH oxidase and peroxidase. Changes in ROS appear to be important in the early stages of signal transduction for many but not all genes.\[8\] Although these pathways are specific for the activation of a particular gene, “cross-talk” between transduction pathways induced by other stress factors must also take place.

Irrespective of the pathway there must eventually be an interaction with the gene involving transcription factors and cis-acting elements within the gene promoter. UV-B–inducible promoter elements and candidate transcription factors have now been identified in plants.\[1,4\] The cis-acting elements for light responsive chs in parsley are called ACE (ACGT-containing elements that recognize common plant regulatory factors) and MRE (Myb recognition elements). Although some differences exist, consistent structural similarities are found in chs promoters between species. A number of other UV-B–inducible transcription factors have recently been identified, including a novel 11-bp, GC-rich sequence identified in the pea sadA and C genes. The sad genes are particularly interesting as they are up regulated rapidly by UV-B and at a relatively low irradiance level. The sad genes are also affected by other environmental stresses, and, therefore, elements in the promoter must be a point of convergence.
for multiple environmental signals. This is supported by an inversely regulated promoter unit that has been identified and responds positively to UV and negatively to a pathogen-derived elicitor. This promoter unit could function as a convergence for largely distinct signal pathways and may also operate through common plant regulatory factors. These and similar studies are being further advanced by the application of rapid throughput screening techniques such as DNA array analysis and suppression subtractive hybridization that can identify UV-B–specific changes in gene activity.

UV-B Defense Mechanisms

Plants have a wide range of protective mechanisms that they use to defend themselves against UV-B radiation (Table 1). One of the first changes that take place in response to UV-B stress is an enhancement in secondary metabolism, particularly in phenylpropanoid-metabolism. This change produces predominantly water-soluble polyphenolic compounds that are synthesized in the epidermal cells. The biosynthetic enzymes are regulated by transcription factors and these may respond to UV-B levels. In addition, in some desert plants hydrophobic derivatives may also be localized in the cuticle. Studies have shown that these compounds are very effective in absorbing UV-B. However, there are substantial differences between species in the degree of UV-B penetration into the underlying mesophyll and palisade tissue. This seems to depend upon a lack of UV-B-absorbing pigments allowing passage through the anticlinal cell walls.

One of the main consequences of UV-B exposure is the generation of free oxygen radicals (e.g., from polyunsaturated fatty acids), leading to a cascade of cellular damage (see the previous section on signal transduction). The plant defense response is to synthesize a number of antioxidants or antioxidant enzymes, such as SOD, catalase, glutathione, ascorbate, flavonoids, or carotenoids. This response is a similar cellular response to that stimulated by many other biotic and abiotic stresses. A more specific change, however, that occurs during UV-B stress is that dihydroxylated flavonoid production is enhanced as they are stronger antioxidants.

A significant difference of UV-B to other stresses, is that UV-B radiation directly impinges on and is absorbed by the DNA of the cell. Many types of DNA lesion are created, but the most common are cyclobutane pyrimidine dimers (CPD) and 6–4 photoproducts. These lesions would have severe consequences for cellular function if not repaired. Most plants have a very effective DNA repair system with light-activated photolyase as the major repair mechanism, dark excision repair enzyme activity also being present. In most studies, DNA damage by exposure to UV-B can be detected, but the repair mechanisms seem to remove the lesions very efficiently.

Overall, the plant defense against UV-B stress depends on protective pigments, antioxidants, and DNA repair mechanisms. Each of these approaches relies on the biosynthesis of enzymes and consequently is dependent on UV-B–induced gene activation. It is apparent that UV-B protection comes at a substantial cost in terms of conversion from primary to secondary metabolism and production of antioxidant systems and repair enzymes. UV-B light appears to stimulate extensive reprogramming of cellular metabolism. This however, is, not as extensive as is the reprogramming induced by pathogens and indicates a clear hierarchy of stress responses with pathogen defense overriding UV-B by selective transcriptional modification of one or more metabolic pathways.

Table 1 UV-B–induced defense mechanisms

- Reflectance by cuticular layer and surface structures.
- Synthesis of UV-B absorbing pigments, primarily in the epidermal layers.
- Changes in gene expression to produce enzymes involved in UV-B defense.
- Production of antioxidant systems to protect against free radical damage.
- DNA repair enzymes activated to remove UV-B–induced DNA lesions.
- Amelioration mechanisms stimulated by other environmental parameters, e.g., high PAR.
INTERACTION BETWEEN UV-B AND OTHER ENVIRONMENTAL FACTORS

The response of plants to UV-B is significantly influenced by the interaction with other environmental factors. There are many examples in the literature[1] and a few examples will be illustrated here. A unique response of plants to UV-B radiation relates to the property of high photosynthetically active radiation (PAR) to ameliorate the damaging impact of UV-B on plants. This was initially discovered at the physiological level, and later molecular studies noted that the down-regulation of gene expression was also reduced by high PAR. This “protection” did not involve synthesis of protective pigments, but was related to the function of the photosynthetic apparatus itself, probably associated with electron transport and photo-phosphorylation.[4] The ability of different wavelengths to modulate the photosynthetic system to sense the external environment and act as a photoreceptor has been documented and can in some instances change chloroplast gene expression.[1] Another important aspect of UV-B–induced changes in gene expression is that it varies depending upon the developmental stage of the tissue. UV-B does not appear to down-regulate genes for photosynthetic proteins in etiolated tissue.[1] Thus, etiolated tissue exposed to light will strongly express genes for chloroplast protein biosynthesis. This expression continues even in the presence of supplementary UV-B radiation. This result is indicative of a strong link between the development of the photosynthetic apparatus and UV-B–induced gene expression. In addition to light quantity, light quality has a strong influence, both at the molecular and the physiological level.

The impact of UV-B stress is also modified by the drought status of the plants. Although some studies show additive effects, most show ameliorating antagonistic interactions. The growth of plants under no-water stress can be severely inhibited by UV-B. However, the same plants exposed to water stress will not be as severely affected. The reduced impact may be due to the drought limiting growth and cell division, consequently limiting the potential of UV-B to damage cellular processes. Other drought stress responses, such as increased levels of osmoprotectants (e.g., proline, GABA, etc.) may also play a role in reducing the impact of UV-B damage. Studies show that the effect will vary on the duration of exposure to both UV-B and drought. In addition, the plant’s genetic background will influence the response. For instance, slow growing ecotypes exposed to these stresses are likely to be more tolerant.

Another interactive stress that has not been extensively investigated is that between UV-B and pathogens/herbivores. Studies have indicated that UV-B–induced changes in plant chemistry can have an impact on pathogens or herbivores. Changes may take place in primary or secondary metabolism to alter the chemical constituents. Such changes could have subtle, but substantial impact on the interactions between a number of trophic levels.[2,3]

SUMMARY

Although substantial progress has been made over the last decade to elucidate the molecular mechanisms involved in UV-B–induced stress responses[1,4,6,14] this area still lags behind comparable areas of plant biology. Through greater knowledge at the molecular level the variation in responses at the whole plant level, plant pathogen/herbivore interactions level, and even at the ecological community level will be understood more fully.

INTRODUCTION

Plant viruses are widespread and economically important plant pathogens. Virtually all plants that humans grow for food and fiber are affected by at least one virus; depending on the plant species, geographic location, growing season, etc., virus disease(s) can preclude the ability to grow specific crops in certain locations. Hence, significant time and monetary resources are invested in efforts to control plant virus diseases. About 80% of the approximately 1000 currently recognized plant-infecting viruses have ribonucleic acid (RNA) as their genetic material. This contrasts with viruses affecting animals and prokaryotes, in which the most common type of genetic material is deoxyribonucleic acid (DNA). This article discusses RNA plant viruses and diseases, factors affecting disease development, and approaches for controlling these diseases.

VIRUS DISEASES IN PLANTS

The natural host ranges of RNA viruses vary from very wide (e.g., Cucumber mosaic cucumovirus (CMV) infects more than 800 species in 85 families) to very narrow, infecting one or a few species (e.g., Apple stem grooving capillovirus). Virus infection results in symptoms that range from no or mild symptoms (latent or cryptic infection) to death of the plant. The symptom type is usually characteristic of the virus, the most common being a mottle or mosaic pattern of light and dark green areas on the leaves delimited by the vein structure; in monocotyledonous plants this results in chlorotic or light green stripes. Mosaic in flowers can give color breaking. Other common symptoms include chlorosis of the leaves, vein clearing, and chlorotic or necrotic ringspots. The most common growth abnormality is stunting; viruses can also cause deformation of leaves, swelling of the stem, and even outgrowths on the underside of leaves. All of these result in reduced yield quality or quantity.[1]

At the cellular level virus infection often causes perturbation of chloroplasts (associated with mosaic symptoms) and disruption or proliferation of membrane systems such as the endoplasmic reticulum. Virus gene products often accumulate to give characteristic inclusion bodies (e.g., the pinwheel structures of infections with Potato virus Y potyvirus (PYV) and related viruses).

DIVERSITY, COMPOSITION, AND REPLICATION

Most RNA viruses have positive-sense single-stranded genomes ((+)-sense ssRNA) (Table 1); the remainder have either negative-sense single-stranded ((−)-sense ssRNA) or double-stranded RNA (ds-RNA). These viruses are classified into genera based on their genome properties, together with characters such as particle shape and biological vectors. Some of the genera with important characters in common are grouped into families. The (−)-sense RNA and dsRNA viruses are closely related to groups of viruses that infect insects and vertebrates.

The particles of most (+)-sense ssRNA viruses are simple, comprising the RNA genome surrounded by subunits of usually a single species of coat protein. There are two basic particle types. In rod-shaped particles, the coat protein subunits are arranged in a helix with the RNA embedded between them. The particles can be either rigid or flexible with a length and diameter characteristic of the genus or family. Rigid particles (e.g., Tobacco mosaic virus (TMV) (300 × 18 nm)) range from less than 100 nm to a few hundred nm in length and flexuous particles from a few hundred to almost 2 microns (e.g., PVY (750 × 13 nm) and Citrus tristeza closterovirus (CTV, 2000 × 12 nm)). The structure of isometric spherical particles is based on icosahedral symmetry, with particles usually comprising 180 protein subunits and having a diameter of 25–30 nm (e.g., CMV); the particles of some viruses, e.g., Tobacco necrosis satellite virus, are smaller (ca. 18 nm) and comprise 60 subunits. Some viruses, e.g., Alfalfa mosaic alfamovirus, have bacilliform particles (25–60 × 18 nm), the structure of which is based on the principles of icosahedral symmetry. The RNA in isometric particles is usually associated with the inner part of the subunits or even with the inner cavity of the particle.
The plant (−)-sense ssRNA viruses have more complex particles made up of protein and lipid and are either spherical (genus *Tospovirus*) or bacilliform (family *Rhabdoviridae*) in shape. The dsRNA viruses also have complex isometric particles comprising two or more layers of different coat protein species.

Many (+)-strand ssRNA viruses, e.g., TMV and PVY, have undivided genomes. However, one unusual feature of other (+)-strand ssRNA viruses is that the genome required for full infection is divided between two and five segments that are packaged into different particles. Thus, the genome of CMV is divided into three segments, each packaged in a separate isometric particle, and that of *Beet necrotic yellow vein benyvirus* (BNYVV) is divided between five rod-shaped particles. The genomes of many (−)-sense ss and ds RNA viruses are divided between several segments, but these are all packaged in the same particle.

RNA viruses replicate by transcribing RNA from RNA. Thus, (+)-strand ssRNA viruses transcribe a (−) strand from the viral template, which in turn is transcribed to give progeny (+) strands. Similarly, (−)-strand ssRNA and dsRNA viruses replicate via a (+)-strand intermediate. Replication is effected by a virus-coded RNA-dependent RNA polymerase (RdRP). The replicate complex comprises RdRP and often a helicase that unwinds double-stranded intermediates and a methyltransferase that caps the 5′ end of the (+) strand.

The genomes of RNA viruses encode the information for virus replication and contain genes for usually five to seven proteins. Those viruses with undivided genomes are faced with the problem of eukaryotic translation systems being able to express only the 5′ open reading frame (ORF). The input RNA of (+)-strand ssRNA viruses acts as an mRNA expressing the genetic information of the virus and giving early virus products such as the RdRP and associated enzymes, the ORFs of which are usually at the 5′ end of the genomic RNA. Downstream ORFs are expressed by processes such as readthrough of stop codons, frameshift from the reading frame of the 5′ ORF, and formation of subgenomic mRNAs during RNA replication. These subgenomic RNAs usually encode late products, e.g., coat protein. The segmentation of the RNAs in divided genome viruses results in most of the ORFs being 5′, thus overcoming the eukaryotic translational constraints.

mRNAs must to be transcribed from the viral genomes for expression of the viruses with (−)-strand and ds RNA genomes. The particles of these viruses contain RdRP, which is used in the early stages of infection to produce mRNAs.

**RNA PLANT VIRUS TRANSMISSION**

Plant viruses must spread among sedentary plant hosts. As viruses lack self-motility, they are dependent on other means for moving from plant to plant; virus movement is effected in several specific ways. By far, the majority of plant viruses are spread by specific, plant-feeding arthropod vectors, mainly Homopteran insects, in particular, aphids; others include leafhoppers, planthoppers, and whiteflies. Some viruses are transmitted by non-Homopterans such as mites, thrips, and beetles. Whereas dispersal by insect vectors is the most common means, a few plant viruses are soilborne, being transmitted by root-feeding nematodes or uncellular, root-infecting fungi.

The ability of a virus to be vector transmitted is determined by specific interactions between the virus and the corresponding vector. However, even among the aphid-transmitted viruses a number of types of interactions exist and significantly affect disease epidemiology. For example, rapid short-distance virus spread is typical for noncirculative aphid-transmitted viruses, whereas circulative viruses that are borne internally within the vector can sometimes be transmitted for the life of the vector. Thus, for the latter, long-distance spread is quite possible.

**CONTROLLING RNA VIRUS INFECTIONS OF PLANTS**

Viruses are molecular intracellular obligate parasites. As such, they are dependent on their hosts’ normal cellular machinery for aspects of their replication and gene expression. Because virus activities are so intimately associated with those of the host cell, opportunities are not readily available for using chemicals (viricides) to interfere with virus infections without also adversely affecting normal host cell metabolism. The most effective approaches for controlling RNA plant virus infections are to avoid or prevent infections.

Avoiding or eliminating sources of virus inoculum is essential for virus disease control, especially if the virus is contained within propagation materials, including seeds or vegetative cuttings. Most woody species (e.g., grapes, roses, fruit trees) are propagated vegetatively and thus, the
simple approach of ensuring that propagation sources are virus-free can provide effective disease control. Many RNA plant viruses such as CTV have been disseminated worldwide by using virus-infected propagation materials. Some viruses are seedborne in crop hosts or in weeds. Both types of host plants can be important for dissemination and subsequent disease development, but if seedborne virus in the crop host is an important source of primary inoculum, then planting seed that is virus-free can provide effective disease control (e.g., lettuce seeds free of \textit{Lettuce mosaic potyvirus} (LMV)). Although eliminating virus inoculum can be very effective, it is not this simple for most plant virus diseases.

Because most plant viruses are transmitted to plants by specific vectors, vector control can also be useful. However, vector control is often expensive and inefficient and may adversely affect non-target organisms. Also, because many RNA plant viruses (particularly those in the genus \textit{Potyvirus}) can be inoculated to plants by their aphid vectors in as little as a few seconds, protective insecticide applications cannot kill aphids before viruses are transmitted, thereby failing to provide disease control.

Host plant resistance (HPR) is a common and often most desirable means for controlling virus diseases in plants. Several important sources of genetic resistance have been identified and are used in crop plants, including beans, tobacco, potatoes, and tomatoes. Although HPR is very desirable and can be very effective (i.e., \textit{N} gene resistance in \textit{Nicotiana} spp. to viruses in the genus \textit{Tobamovirus}), there are limits to its usefulness. For example, \textit{N} gene resistance is specific, and thus effective against most tobamoviruses but not against unrelated viruses. Although the \textit{N} gene can be transferred among related \textit{Nicotiana} spp. by conventional plant breeding, it cannot be similarly transferred to unrelated species lacking effective resistance genes (i.e., cowpeas (\textit{Vigna unguiculata}) for \textit{Sunnhemp mosaic tobamovirus}). In other instances, HPR may be multigenic, and can be very difficult to effectively manipulate.

In recent years genetically engineered resistance has been shown to be a powerful, and potentially very useful, alternative strategy that can complement other approaches to controlling virus diseases in plants. A good source of antivirus resistance genes has proven to be the viruses themselves. By expressing in plants, genes, or gene fragments derived from RNA virus genomes, very high levels of resistance against the donor virus have been obtained. This approach has worked experimentally for many different viruses in several plant species, although only a few genetically engineered virus-resistant plants have been used so far in commercial agriculture. One good example is resistance in papaya (\textit{Carica papaya}) to \textit{Papaya ringspot potyvirus} (PRV) in Hawaii.\cite{2} The use of genetically engineered resistance so far appears very promising for complementing other approaches to virus disease control in plants.

\textbf{CONCLUSION}

Virus infections continue to be a serious constraint on crop production in spite of the wide range of control measures in use. The application of new technologies such as genetic manipulation and genomics should lead to more successful ways of controlling viruses. These will be of particular importance in developing countries where losses due to viruses are relatively great.

The study of the interaction of plant viruses with their hosts has already led to greater understanding of how plants function at the molecular level. With the increasing sophistication of molecular technologies, it is likely this will continue at an ever increasing rate. RNA viruses will play a major role in this, especially in understanding defense systems against foreign RNAs.\cite{3}

INTRODUCTION

The U.S.A. has several types of intellectual property rights that apply to plant cultivars or varieties. Plant Variety Protection (PVP) is handled by the U.S. Department of Agriculture (USDA), PVP Office. A PVP is similar to plant breeders’ rights in other International Union for the Protection of New Varieties of Plants [known by its French acronym (UPOV)] countries; however, in U.S.A., eligibility for PVP is limited to seed- or tuber-reproduced plant varieties. Varieties need to be new, distinct, uniform, and stable to be granted a PVP Certificate. Once granted, the breeder has exclusive marketing rights for a limited time. This allows breeders to recover the costs of research and development, and encourages them to reinvest in agricultural breeding work.

APPLICATION FOR PVP

Plant breeders may take 10–15 yr to develop a new plant variety, but the variety’s market life can be as short as 2–5 yr. Breeders, and the companies they work for, use intellectual property rights protection to control the marketing of their new varieties. This extends the period in which the owner can benefit from having developed the variety, thus allowing for potential recovery of their research and development costs.

If the variety is sexually reproduced or tuber propagated, the breeder may apply for PVP. “Tuber” is used in its most strict botanical sense, examples of which include potato, anemone, caladium, and oxalis. Inbred lines, open-pollinated or self-pollinated varieties, synthetic populations, hybrids, and genetically modified plants are eligible for PVP, but bacteria and fungi are excluded. For vegetatively reproduced plant species, there are other means of protection such as plant patents administered by the U.S. Patent and Trademark Office. Please read elsewhere for information about other forms of protection.

In the application, the applicant must demonstrate that the variety is new, distinct, uniform, and stable. These are the same standards used by UPOV. The applicant is responsible for conducting the tests for distinctness, uniformity, and stability (DUS), analyzing the data, and reporting information to the PVP Office. Examiners base their decisions on the information contained within the application. Unlike some other UPOV member countries, no site visits or government testing are performed in U.S.A. Therefore, the completeness and quality of the application is important to the decision-making process.

An application consists of three parts: paperwork, fees, and a voucher seed sample. The paperwork has six sections. Necessary forms can be obtained from the PVP Office, which also can offer advice and guidance in preparation of an application. The application form serves as a cover sheet for the application. The form requests such information as name of the applicant, whom to contact during processing, the identity of the crop and variety, administrative details, and whether the variety is new. To establish that the variety is new, the applicant must indicate that the variety, or a hybrid produced from it, has not been exploited for more than one year in U.S.A. or more than four years in a foreign country (or six years in a foreign country in the case of a vine or tree). The applicant signs at the bottom of the form to attest to the truthfulness of all reported information.

Exhibit A contains a full description of the breeding history of the variety. The variety should be “finished” when the applicant applies for protection. There should be no further need for cleaning up the variety, doing further generations of selections, or otherwise changing the genetic composition of the variety.

Toward the end of the Exhibit A, the applicant needs to state whether the variety is uniform and stable, and how this was determined. Uniformity must be considered for the variety as a whole, not just for the traits of interest. For example, being uniform for herbicide tolerance would not be acceptable if all other traits of the plants were excessively variable. A finished variety should be stable over the course of maintaining the variety through repeated generations of reproduction. So, stability should be tested by maintaining the finished variety through three or more generations.

In the Exhibit A, applicants are required to include a statement about known or expected genetic variants. There should be no off-types, other species, or other varieties contaminating the seed stock, because these should have been removed during the breeding and
cleaning processes. There should be very few genetic variants expected when the variety is reproduced over time, and the level of purity that is acceptable depends on the specific breeding method that was used. Some breeding methods can produce almost homozygous seeds, given enough generations of selfing and selection. Other methods cannot attain such a high level of purity, and perhaps as much as 5% genetic variants may be considered acceptable in these cases.

In addition to the statements made in the Exhibit A concerning uniformity, stability, and variants, the examiner will study the rest of the application to determine whether the variety is sufficiently uniform and stable for the reproductive method used to create the variety and maintain it over time. Mixtures and blends, by their very nature, are not uniform or stable. Special circumstances govern the uniformity of hybrids and synthetic varieties, for which there is not sufficient space in this entry to describe adequately.

Exhibit B contains the claims and supporting evidence for the distinctness of this variety. Several formats for this document are acceptable, but the easiest format is one in which the new variety is compared to one or a few most similar comparison varieties. The applicant then states how the application variety differs from the most similar varieties, using objective data to support the claims. Supporting data may include statistical analyses for quantitative differences; color chart values for color differences; photographs for qualitative differences; biomolecular assays showing presence or absence of genes, proteins, or enzymes; laboratory test results; genetic fingerprints; or other types of verifiable test results. The claims and data contained in Exhibit B are heavily scrutinized, because this document provides much of the evidence used to make a final decision about DUS for the application variety.

The Exhibit C form is used to objectively describe the application variety. The PVP Office has created over 100 crop-specific objective description forms. New forms are created if the form is expected to be used regularly in the future. A general form for use with any species has been developed to accommodate first applications in crops that are new to the PVP Office.

Exhibit D is an optional document used for additional description of the variety. Applicants have used this section of the application to report extensive statistical analyses, genetic fingerprinting, or agronomic performance information.

The Exhibit E form guides the applicant in attesting to the breeder’s ownership and eligibility to apply for PVP. If the rights to the variety have been transferred to another person or company, the ownership changes need to be explained. Eligibility requirements include the nationality of the applicant. US citizens, residents, and companies, or citizens, residents and companies of other UPOV member countries are eligible to apply for PVP in U.S.A. Applicants from countries that are not UPOV members may apply; however, they must first demonstrate reciprocity with a sui generis law which grants intellectual property rights to plant varieties. Ninety percent of applicants are from U.S.A., of which 15% are from US public institutions such as universities or government agencies (Fig. 1). Only 10% of applications are received from foreign applicants.

The PVP Office is completely user-fee funded. Fees collected from applicants and other users of services are used to pay salaries, rent, supplies, and other costs of doing business. The fee schedule is available in the PVP Act’s Regulations or on the PVP Web site. The fees for filing and examining the application must accompany the application packet.

A voucher seed sample is required for all seed-reproduced application varieties at the time of filing the application. There is a new procedure for direct deposit of the seeds in the approved seed repository. When using the direct deposit option, applicants will be asked to supply the seed sample within 3 mo after the filing date of the application. Tissue cultures for tuber-propagated varieties need to be provided at the time of issuance of the PVP Certificate. The seeds and cultures are stored at the National Center for Genetic Resources Preservation in Fort Collins, Colorado, U.S.A. A phytosanitary certificate is required for samples that are imported into U.S.A.

Processing of Applications

Applications are reviewed for completeness and internal consistency. Descriptive data is entered into crop-specific data tables to allow examiners to search for previously existing varieties that may prevent issuance of the certificate. The examiner will correspond with the applicant to clarify information contained in

Fig. 1 Nationality of Plant Variety Protection applicants. Most applicants (75%) are US companies or individuals, often referred to as the private sector. The public sector (universities and government) accounts for 15% of applications. (From PVP Office data). (View this art in color at www.informaworld.com.)
the application or acquire missing information. Once the applicant has demonstrated that the variety is new, distinct, uniform, and stable, the examiner writes a report, which includes a recommendation that a certificate of protection be issued. The work of the examiner is reviewed and approved by the PVP Commissioner. Certificates are signed by the PVP Commissioner and the Secretary of Agriculture (Fig. 2).

Essentially derived varieties were given legal status in the 1991 UPOV Convention. PVP examiners do not consider whether a variety is essentially derived from another variety when making their decisions to grant PVP Certificates. The only criteria considered are whether the variety is new, distinct, uniform, and stable.

A PVP Certificate grants the owner exclusive marketing rights for 20 yr (25 yr in the case of trees and vines). These rights cover harvested material of the variety, varieties that are indistinct or essentially derived from the variety, and varieties that require repeated use of the protected variety. There are two exemptions to these rights: one allows farmers to save seed of the protected variety for use in their own farm; the second allows researchers to use the protected variety in plant breeding or other research.

The PVP Office receives approximately 300 new applications a year. The majority of applications are for agricultural crops such as soybean, maize, and wheat (Fig. 3). Applications are assigned to one of seven examiners, who have expertise in their assigned crops and who make the decisions whether to grant PVP Certificates. They are assisted by three support persons, who handle data entry and routine correspondence, and a computer specialist, who maintains the computer resources. The office is supervised by the PVP Commissioner who has responsibility for the quality and completeness of the examiners’ decisions.

The total time needed to process an application depends on the quality and completeness of the application, and the amount of time needed for literature research and updates to the data tables. Seventy-seven percent of applications are processed in less than 36 mo. Applications of higher quality can be processed faster, and poorer quality applications take more time (as much as 10 yr). The longer times often indicate multiple opportunities when the applicant was asked to amend the application to establish that the variety was new, distinct, uniform, and/or stable.

Typically, 84% of applications result in the grant of a PVP Certificate (Fig. 4). Most of the remaining applications are either abandoned or withdrawn by the applicant. Rarely is an application denied (18 applications; average processing time was 61 mo) or declared ineligible (75 applications; average processing time was 19 mo). Ineligibility is often based on the variety not being new or the applicant not being eligible. Denial is usually based on the variety being indistinct from previously existing varieties. A few denials were based on non-uniformity or instability of the variety.

![An issued PVP Certificate](Fig. 2) (View this art in color at www.informaworld.com.)

![Types of crops that are filed for PVP. Agricultural crops, such as maize, soybeans, and wheat, account for 75% of PVP applications of the 300 applications received each year. Tubers became eligible for PVP in 1995. (From PVP Office data.)](Fig. 3) (View this art in color at www.informaworld.com.)
CONCLUSIONS

PVP provides a unique form of intellectual property rights specifically designed for plants. It incorporates the legal criteria established by UPOV, and the examination process mimics patent examinations. The technical review of applications focuses on the scientific details of the development and description of the variety, which makes the application preparation meaningful for plant breeders and scientists. The rights granted by a PVP Certificate allow the owner of the plant variety to recover research and development costs by controlling the marketing of the variety.

INTRODUCTION

Synergism is one of the many interactions that may occur between viruses that affects both the expression of disease and the replication of the viruses involved. In medical virology the occurrence of synergism is relatively rare, as the occurrence of two viruses in vertebrate cells is rather uncommon outside of laboratory cell culture. With plant viruses, however, the phenomenon of synergism has been noted since the early days of plant virus research in the 1920s. Synergism was intermittently studied until the tools of molecular biology became available to dissect this interesting virus interaction. Posttranscriptional gene silencing is now thought to modulate the virus replication and accumulation resulting in a synergistic interaction between plant viruses.

INTERACTIONS BETWEEN PLANT VIRUSES

A number of interactions may occur between plant viruses. Cross-protection refers to the protection of a plant by a mild strain of a virus from a related severe strain. When plant viruses are inoculated concurrently, a protection may ensue that results from the reduction of replication rate or final quantity of the challenge virus. Satellite viruses or satellite RNAs require a helper virus to replicate, but generally satellites do not have much sequence homology with the helper virus. The symptomatic outcome is usually a reduced severity of disease, although there are many exceptions involving satellites where in more severe disease symptoms are expressed. The outcome of a synergistic interaction between plant viruses, however, is by definition a more severe expression of disease than either virus alone or the expected additive effect produced by the infection of two viruses. In addition, the increase in symptom severity is usually associated with an increased accumulation of one or both of the coinfesting viruses.

SYNERGISTIC INTERACTIONS ARE NOT LIMITED TO A FEW VIRUSES

The literature is replete with examples of synergism between different plant viruses that include viruses with genomes of RNA or DNA. Some interactions that have been noted are significant in the field, resulting in severe and recurring losses to producers; others are limited to the greenhouse; and some are laboratory oddities that have been produced by inoculation with viruses that normally would not be found in the same host plant. The model system that has been most frequently investigated is the interaction that occurs between Potato X virus (PVX), a species in the Potexvirus genus, and Potato Y virus (PVY), a species in the Potyvirus genus, family Potyviridae (Fig. 1). PVX and PVY were noted to cause a severe symptom in potato coined “crinkle,” “rugose mosaic,” and “streak.” Initial investigations of this system elucidated that both viruses replicated in the same cells, and an increase in the amount of PVX detected was likely due to an increase in the amount of virus produced. PVX has no allegiance to PVY in producing a synergistic interaction, and coinfection with a number of Potyvirus species (including Tobacco vein mottling virus (TVMV), Tobacco etch virus (TEV), or Pepper mottle virus) all result in a synergistic manifestation of disease.

A CONVERGENCE OF IDEAS LEADS TO INSIGHT INTO THE MECHANISM OF SYNERGISM

Gene Silencing

With the advent and common availability of methodology and reagents for gene cloning and plant transformation, a myriad of transgenic plants was produced with a variety of virus gene constructs, with the goal of overexpression of the gene of interest. In many of the experiments, however, the outcome was the opposite of what was anticipated, and gene expression was suppressed. A number of terms have been used in the literature to describe this phenomenon, including cosuppression, RNA interference (RNAi), posttranscriptional gene silencing (PTGS), sense suppression, quelling, and virus-induced gene silencing (VIGS). Double-stranded RNA (dsRNA) is a key component of the proposed pathway by which RNA silencing occurs, and dsRNA is a key component during replication of RNA plant viruses. RNA silencing has been extensively reviewed and will therefore be only briefly treated.
here. RNA silencing is a naturally occurring mechanism of genetic regulation in eukaryotes that is directly targeted at nucleic acid. It can be induced by viruses, transgenes, or the transcripts normally produced in the plant that result in the formation of dsRNA. The dsRNA is acted upon by an enzyme coined DICER that processes the dsRNAs into short (approximately 25-nucleotide) RNAs. The small interfering RNAs (siRNA) derived from the processing of the dsRNA enters into a RNase complex, RISC (RNA interference specificity complex), that further mediates sequence-specific RNA degradation. Associated with gene silencing is a mobile signal that may move throughout the host plant and hence act as the systemic signal in gene silencing. It has also been noted in plants that methylation of the transcribed region is associated with gene silencing, a state that may be recurring in subsequent generations of an affected organism and may be the basis for maintaining the gene silencing.

This system is of great interest because the silencing signal can function in other points in the plant wherein the cascade of events was initiated. The unfolding understanding of the parameters that modulate RNA silencing provides an exciting avenue for the regulation of gene expression, from transgenes or endogenous genes.

**Potyvirus and Potexvirus Genomes**

Virions of the members of the Family *Potyviridae* are a long, flexuous particle whose size ranges from 650–900 nm in length and 11–15 nm in diameter. Most have a single-stranded plus-sense RNA that codes for one polyprotein that is cleaved into a number of proteins. The replication strategy and viral genome are well characterized, as the order of the proteins in the polyprotein and their function have been extensively studied.[2] The 5′ terminus encodes protease-1 (P1, molecular weight 35K), helper component protease (HC-Pro, molecular weight 52K), and protein-3 (P3, molecular weight 50K). P1 is involved in the processing of the polyprotein, as is HC-Pro, which is also involved in transmission of the virus by aphids. Virions of the genus *Potexvirus* have flexuous particles about 470–580 nm long and 13 nm in diameter. The viral RNA is a single-stranded plus-sense RNA. However, unlike members of the Family *Potyviridae*, one protein—the replicase—is produced from the genomic RNA for members of the genus *Potexvirus*; other proteins are produced from subgenomic RNAs that are produced during virus replication.

**Synergism**

To elucidate the nature of interaction between PVX and members of the *Potyviridae* that result in a synergistic interaction, tobacco was transformed to express a variety of portions of the genome if TMV or TEV were challenge-inoculated with PVX. Transgenic plants expressing the 5′-proximal region of the TMV genome that included the P1, HC-Pro, and P3 genes were challenged with PVX, resulting in symptoms typical of the PVX-*Potyviridae* synergism. Typical synergistic symptoms were also observed when transgenic tobacco plants expressing the similar 5′-proximal region of the TEV genome were inoculated with PVX. Hence, the interaction was linked to the 5′-proximal end of the potyvirus genome. Subsequent investigations showed that the P1 and P3 regions were not necessary for the synergistic symptoms to be produced, as expression of HC-Pro alone could facilitate the synergistic interaction.[8] In addition, expression of HC-Pro was found to enhance the
accumulation of *Cucumber mosaic virus* and *Tobacco mosaic virus*. These viruses are unrelated to PVX; thus HC-Pro appears to act to enhance virus replication irrespective of the infecting virus.

The enhancement of virus replication in the synergistic interaction appears to result from the suppression of gene silencing. During unaltered virus replication as dsRNA is produced, the natural defense mechanisms of plants likely modulate the accumulation of virus through PTGS as briefly outlined in the foregoing. As the dsRNA are not processed, resulting in the production of the siRNAs necessary for the degradation complex, the resulting accumulation of PVX appears to result in the synergistic interaction and severe symptoms.[9] Grafting experiments indicate that the mobile silencing signal continued to be produced, and thus is not dependent on the production of the small RNAs.

**CONCLUSION**

Although the possible basis of synergism has been partially unveiled, there remains much to understand about the applied aspects mitigating the effects of synergism in the field. The epidemiological consequences synergism has been modeled, and viruses sharing an infected host may be in a perplexing ecological dilemma.[10] Increased symptom severity can result in reduced availability of the host, whereas increased replication and increase in virus titer may represent greater opportunity for subsequent transmission. In regard to disease management, severe symptom expression is generally accompanied by loss of plant yield and quality. Hence, the basis of synergism must be determined so that it can be effectively managed to address recurring problems.

INTRODUCTION

Plant virus taxonomy has been perhaps the only area of the science of virus systematics where most of the rules of the International Committee on Taxonomy of Viruses (ICTV) are followed. In fact, plant virologists have led the way a number of times in the last 40 years in establishing and testing criteria for virus systematics as a result of that cohesion, and the trend continues with the latest proposals for nomenclature. The result is a more or less uniform set of descriptive virus names, and an essentially unified set of criteria for determining familial, generic, and species membership. Inasmuch as taxonomy consists of classification plus nomenclature, the core criteria for assigning new plant viruses to a taxon, the latest consensus on nomenclature and orthography, and problems in plant virus taxonomy are described in this entry.

PLANT VIRUS CLASSIFICATION

Viruses are classified into taxonomic orders (suffix: virales), families (suffix: viridae), subfamilies (suffix: virinae), genera (suffix: virus), and species. The official publication of the ICTV on virus taxonomy—now the eighth report—lists 3 orders of viruses, 73 families, 9 subfamilies, 287 genera, and 1938 virus species. Of these, only 16 families (and no orders or subfamilies) contain plant-infecting viruses; 61 genera in these families, together with viruses from 17 unassigned genera, give a total of 797 recognized species of plant viruses. There are also two official families of the circular ssRNA viroids, with 7 genera and 28 species, as well as 4 satellite virus species. While there are no officially recognized satellite nucleic acid species, there are two ssDNA and ssRNA entities grouped into four distinct categories. The currently accepted list of plant virus families and genera, satellite viruses and viroids, as well as satellite nucleic acids are illustrated in Table 1.[1,2]

Families and Genera of Plant Viruses

The ICTV website (http://www.ncbi.nlm.nih.gov/ICTV/) lists the following as the criteria defining taxonomic families and genera.

- Family: common properties between several genera including
  - Biochemical composition.
  - Virus replication strategy.
  - Nature of the particle structure.
  - Genome organization.

- Genus: common properties within a genus including
  - Virus replication strategy.
  - Genome size, organization, and/or number of segments.
  - Sequence homologies (hybridization properties).
  - Vector transmission.

More detailed familial criteria are given at the ICTV website; these include many more specific properties such as type and strandedness of genome, number of genome segments, and number and size of proteins (http://www.ncbi.nlm.nih.gov/ICTV/Descriptors.html).

The exact criteria for any given genus are operationally defined on the basis of observations made by members of the defined ICTV Plant Virus Subcommittee Study Groups. For example, the study groups have had to make decisions on whether the number of genome components is more important than the type of vector which transmits the viruses, or, where there is a known vector, how much of a taxonomic criterion this is. While the number of genome components is a major criterion for potyviruses, for example, only generic begomoviruses have two components, while all other potyvirus genera have only one, there are several generic begomoviruses in family Geminiviridae which have one genome component while the rest have two.[1]

Species of Plant Viruses

The concept of a viral species has long bedeviled the taxonomic virology community, largely because of the fact that viruses do not replicate like cellular organisms, and classical definitions simply did not fit. However, it is now accepted that “A virus species is a polythetic class of viruses that constitute a replicating lineage and occupy a particular ecological niche.”[1] Operationally, defining a virus species is probably even more a family and genus-specific process than for

(Data from Dr. M. J. Adams, ICTV Plant Virus Subcommittee, Rothamsted Experiment Station, BBSRC, U.K.)
defining genera. For example, in the Geminiviridae species demarcation criteria are as follows:

- Different numbers of genome components.
- Different organization of genes in the genome.
- No transcomplementation of gene products.
- No pseudorecombination between components.
- Nucleotide sequence identity (<75% for mastreviruses, <80% for curtoviruses, and <90% for begomoviruses).
- Virions react differently with key antibodies.
- <90% coat protein gene sequence identity.
- Different vector species.
- Different host range/pathogenicity.[4]

Note that in genus Begomovirus, a viral species is defined as a virus having at most 89% total DNA sequence similarity to any other defined species, whereas in genus Mastrevirus, the difference in a species may be as large as 25%, given a more similar biology between these viruses than between begomoviruses, and greater potential for trans-replication across the sequence divide. Thus, the same criteria are not rigidly applied across genera, and a balance may be struck between sequence-defined and biologically defined properties.

PLANT VIRUS NOMENCLATURE AND ORTHOGRAPHY

Rule 3.40 of the International Code of Virus Classification and Nomenclature reads: “Species names are printed in italics and have the first letter of the first word capitalised. Other words are not capitalised unless they are proper nouns, or parts of proper nouns.”[3] This format is, however, used only when referring to an official taxonomic entity, or taxon—otherwise one would refer to, for example, “tobacco mosaic virus replicase,” or “purification of cucumber mosaic virus.”[5] When writing a paper, it has become a convention to initially define the viruses one works with by familial, generic, and species definitions, and thereafter by acronym or by common name. As an example, a particular geminivirus would first be referred to in text as belonging to species Bean golden mosaic virus-Puerto Rico (BGMV-PR; genus: Begomovirus, family: Geminiviridae), and thereafter called BGMV-PR or simply BGMV. A comprehensive list of plant virus names and abbreviations is given in Refs.[1,6]

PROBLEMS IN PLANT VIRUS TAXONOMY

With the increasing ease of DNA sequencing have come an explosion in complete genome sequencing of plant viruses and an increase in reliance on the use of sequence rather than on more classical properties to classify them. The use of sequence has allowed genetic distinctions to be made between viruses that otherwise apparently share biological properties, to the point of being almost indistinguishable. Among begomoviruses in the species Tomato yellow leaf curl virus (TYLCV), for example, Tomato yellow leaf curl Sardinia virus (TYLCSV) and Tomato yellow leaf curl Thailand virus (TYLCTV), all cause similar disease, but are genetically distinct, and, in the case of TYLCTV, have two genome components rather than one.[4] This has led to a problem of naming viruses that may have been called the same thing or strains of one species, but are later shown to be distinct species. For example, East African cassava mosaic virus (EACMV) was so named to distinguish it from African cassava mosaic virus (ACMV) after sequencing revealed the distinction; later, a necessity arose to similarly distinguish East African cassava mosaic Tanzania virus and EACMV Malawi virus from each other and from EACMV.[4] This may prove difficult to do in future, and new rules may be needed for naming of species.

CONCLUSIONS

As with all virus taxonomy, plant virus sytematics is a work in progress: it will change from year to year, and may change radically without warning. However, it remains a system of rules which is amenable to suggestion, while at the same time striving to offer logical ways to order a very varied group of organisms.

Plant Virus Replication

M. Shanks
G. P. Lomonossoff
John Innes Centre, Norwich, United Kingdom

INTRODUCTION

Viruses are important causative agents of plant disease. Although crop losses due to viruses are difficult to quantify, it has been estimated that damage caused by a single viral disease, the ‘‘Tungro’’ disease of rice, costs in the region of US$1.5 billion per year in Southeast Asia alone. In plants, as in prokaryotes and animals, there is a wide diversity of viruses in terms of the host range, their mode of infection, morphology, etc. Although it is possible to classify viruses according to these characteristics, it has become increasingly apparent that the fundamental nature of a virus is best described in terms of its mode of replication rather than its phenotypic properties. In this section we review the replication strategy of all currently known plant viruses and highlight their classification based on the ‘‘Baltimore scheme.’’

THE BALTIMORE CLASSIFICATION SCHEME OF VIRUSES

A virus is an organism that contains genetic material surrounded by a protein shell and, in some cases, a lipid envelope. All viruses are intracellular parasites and have an absolute dependence on the host. Whereas host cells exclusively have double-stranded DNA as their genetic material, viruses can have genomes consisting of either DNA or RNA, and this, in turn, can be either single- or double-stranded. This variation has led to a scheme, known as the ‘‘Baltimore scheme’’ (after its originator David Baltimore). This scheme classifies all viruses, regardless of host or particle morphology, according to their genome structure and mode of replication. The basis of the classification scheme is that it attaches central importance to the stage in the viral replication cycle where messenger RNA (mRNA) is synthesized. In its original form, the Baltimore scheme recognized six classes of viruses, but this has been subsequently revised to include a seventh. Classes 1 and 2 consist of viruses which have DNA genomes and which replicate via the classic semiconservative method. Class 1 consists of viruses that have double-stranded (ds) DNA genomes and which replicate via the classic semiconservative method. Somewhat surprisingly there are no plant viruses within this class, although over 20% of plant virus genera have genomes based on DNA rather than RNA. By contrast, class 1 accounts for over 75% of the virus genera found in bacteria (including the T-even and lambda phages of Escherichia coli) and 26.5% of viruses in higher animals (e.g., the pox and herpes viruses). Under the original Baltimore classification scheme, the Caulimoviridae family was assigned to class 1. However, it was subsequently found that this family of viruses, although encapsidating ds DNA, replicates through a mechanism involving an RNA intermediate and a new class had to be created to accommodate them (class 7, see below).

Class 2

Class 2 encompasses those viruses which encapsidate single-stranded (ss) DNA. The replication of these viruses requires the formation of a ‘‘replicative-form’’ (RF) ds DNA intermediate soon after infection. It is from the RF DNA that the virus-specific mRNA is transcribed (Fig. 1). There are two families of class 2 type virus which contain plant-infecting genera, the Geminiviridae and the Circo- viridae. The Geminiviridae have circular ss DNA genomes of a total size of 2.7–5.4 kb depending on whether they are mono- or bicomponent viruses. The DNA is replicated by the rolling-circle mechanism. The
family Circoviridae contains genera which infect both animals (circoviruses) and plants (nanoviruses). The nanoviruses have genomes that consist of 6–10 segments of circular ss DNA, each of approximately 1 kb in size and encoding a single protein. The precise number of segments that make up a complete nanovirus genome is not clear.

**Class 3**

Class 3 consists of viruses that have ds RNA genomes. The process of transcription to produce the viral mRNAs is analogous to that from ds DNA. However, the enzymes necessary to carry out this process from an RNA template are missing in an uninfected cell. Thus this group of viruses must encode an RNA-dependent RNA polymerase (RdRp), which is packaged within the virion and is introduced into the host cell at the same time as the genome. There are two families of plant-infecting class 3 viruses, the Parititiviridae and the Reoviridae. Members of the Parititiviridae family have genomes consisting of two segments of linear ds RNA of 1.4–3.0 kb and exclusively infect plants. Reoviridae have multicomponent genomes (typically 10–12 segments of ds RNA) with all segments being encapsidated in a single shell. The total genome size is approximately 18–30 kbp. There are genera of the family Reoviridae which infect either animals or plants. The plant-infecting genera are able to replicate in their insect vectors.

**Class 4**

Class 4 viruses have genomes that consist of one or more segments of ss RNA of positive-strand (mRNA-sense) RNA. By far the largest proportion of plant viruses (65%) falls within this class. This class also has members which infect animals and bacteria. The RNA within the particles can immediately act as mRNA upon infection, and provided it can be delivered to appropriate cells, RNA isolated from virus particles is directly infectious. Upon uncoating, translation of the viral RNA using the host-encoded translation machinery rapidly ensues. One of the earliest products produced is the viral RdRp, which synthesizes complementary sense (so-called “minus-strand”) RNA using the viral (“positive-strand”) RNA as a template. A replication complex is then produced which maintains a balance between minus-strand, positive-strand, and double-stranded (i.e., − and + strand) RNA molecules. A bias in the complex favors the production of positive-strand molecules and synthesis of the viral structural proteins. The coat protein(s) and positive-strand RNA assemble, and mature virions are produced. At present 48 genera of plant viruses are classified as class 4. These include viruses which have either one or several genome segments, and particles which have either isometric or rod-shaped morphologies.
Class 5

Class 5 viruses have genomes that consist of one or more segments of ss RNA that is of the complementary sense to the mRNA. RNA extracted from such “negative-strand” viruses is not directly infectious. On entry into a host cell, the virion RNA is transcribed by a virus-derived RdRp to give the mRNAs which can be translated to give the virus-specific proteins. In a manner similar to that found with class 4 viruses, a replication complex is formed, but in this case there is probably a bias for production of full-length positive-sense RNA and subsequent generation of genomic (negative-strand) RNA. There are two families (the Bunyaviridae and Rhabdoviridae) as well as some unassigned genera which infect plants. Both families also contain genera that infect animals. Members of the tospoviruses, the plant-infecting genus of Bunyaviridae, have tripartite genomes, whereas members of the Rhabdoviridae family are nonsegmented.

Class 6

This group contains viruses which encapsidate ss RNA molecules of positive (mRNA sense) polarity. However, unlike class 4 viruses, the RNA replicates via a ds DNA intermediate which becomes integrated into the host genome. While viruses of the family Retroviridae are extremely important animal pathogens, there are currently no class 6 plant viruses recognized.

Class 7

Viruses in class 7 encapsidate ds or partially ds DNA molecules and replicate via an RNA intermediate. They are known as “pararetroviruses” to distinguish them from retroviruses which encapsidate RNA. There are two families in this class, the Hepadnaviridae (which infect animals) and the Caulimoviridae (which infect plants). In the case of the Caulimoviridae, the ds circular genomic DNA is about 8 kb and is directly infectious. Once inside the nucleus of the host cells, the DNA is transcribed by a host-encoded RNA polymerase to produce positive-sense RNA. These molecules act as mRNAs for the synthesis of the virus-specific proteins and also as a substrate for the virus-encoded reverse transcriptase, to produce new copies of the genomic ds DNA. These molecules act as mRNAs for the synthesis of the virus-specific proteins and also as a substrate for the virus-encoded reverse transcriptase, to produce new copies of the genomic ds DNA. For many years it was believed that the genomes of the family Caulimoviridae did not integrate into the host genome. However, more recent work with the members of the genus Badnavirus has shown that integration does indeed occur and may play a significant part in the spread of the viruses.

CONCLUSION

This article has discussed the replication of plant viruses in terms of the “Baltimore scheme.” This is a simplified and unified approach which stresses the similarity between different viruses rather than their differences. It
has not been the purpose of this review to cover in great
detail the genome structures or taxonomy of the various
virus families and genera, which is comprehensively
covered by the seventh report of the ITCV.\[2\] Similarly,
for further information relating to the general description
of the plant viruses the reader is referred to the web-based
databases that are available.\[4,5\]

INTRODUCTION

In order for plant viruses to survive in nature, they must spread from infected plants to susceptible plants. Because plant viruses are unable to penetrate the protective layer (cuticle), viruses must be deposited into plant cells before infection can occur. Viruses may be introduced through a wound or from an infected plant through seed or pollen from the infected plant. The use of plant parts, such as tubers or stem pieces, from infected plants for vegetative propagation or grafting results in the spread of viruses to progeny and grafted plants. Many plant viruses depend on another organism, called a vector, which penetrates the cuticle of plants and acquires and transmits the virus during feeding. Vectors for plant viruses include invertebrates, such as aphids, whiteflies, leafhoppers, beetles, mites, and thrips, and nematodes and fungi. Viruses usually have only one type of vector under natural conditions, but a virus may spread by several means, e.g., by seed and aphid transmission. Transmission of plant viruses by various means is important to their dispersal and survival and plays a critical role in their epidemiology. Determining the means by which a plant virus spreads in the field is essential for development of effective disease management strategies.

MECHANICAL TRANSMISSION

Transmission of viruses by contact between infected and healthy plants is relatively rare in nature and occurs with only a few very stable viruses that reach high concentrations in plant cells. When an infected plant rubs against a healthy plant and causes a wound, sap from the infected plant can enter the wound and infect the healthy plant. Tobacco mosaic virus is readily transmitted from infected tomato plant debris to healthy tomato seedlings when the roots of seedlings are wounded during transplanting or as they grow in the soil. This stable virus is also readily transmitted on equipment and the hands of workers that have been in contact with virus-infected plants. Management of this type of transmission is through the use of clean soil and equipment and thorough hand washing.[1]

SEED TRANSMISSION

Virus transmission through seed is an effective means for virus survival while a crop is not being grown and for establishment of virus-infected seedlings randomly throughout a field early in the season. Seed transmission of viruses is relatively rare in that only about 15% of plant viruses have been reported to be seed-transmitted in one of their hosts.[2] The percentage of seeds from infected plants that give rise to virus-infected seedlings is usually small, although in some cases, 100% seed transmission has been reported. Even with low levels of seed transmission, extensive crop infection and economic loss may result if natural transmission by another means, such as with an insect vector, occurs during the growing season. Seed transmission is also a potential problem in the international spread of viruses through commerce of infected commercial seed.

Seed may become infected with virus through an infected mother plant or through pollen from a virus-infected plant. Seedlings from infected seed become infected in one of two ways: 1) the virus is found within the tissues of the embryo that gives rise to the seedling; 2) the virus is transmitted on or in the seed coat, and the growing embryo becomes infected during germination or transplanting. When infection of the seedling occurs from virus contamination of the seed coat, the virus can be eliminated by seed treatment with hydrochloric acid or trisodium orthophosphate.[3] For viruses found in the embryo, the production and use of virus-free seed is an effective management strategy when seed transmission is the main or only source of the virus for the crop. A good example of the effectiveness of this strategy is the use of virus-free seed to control Lettuce mosaic virus in lettuce in California.[4] Programs such as these require strict guidelines for seed production and sensitive assays to test for the presence of virus in batches of seed.

VECTOR TRANSMISSION

Plant virus vectors are the main means by which many economically important viruses are spread in the field.[2] A diverse group of organisms is capable of transmitting

An important characteristic of all plant virus vectors is that they break the cuticle and cell wall of the plant and introduce virus into the cytoplasm of plant cells. Some vectors, such as aphids, nematodes, and whiteflies, accomplish this through a specialized feeding apparatus called a stylet that is used to penetrate the plant cuticle and cell wall. The viruses are acquired from infected cells during feeding when the vector ingests cell contents through the stylet, and subsequently, the viruses are deposited into a plant cell as vectors insert their stylet and salivate into the cell during feeding. Viruses that are transmitted by fungi are introduced into root cells when virus-carrying zoospores penetrate the cuticle and cell wall during fungal infection.

Plant viruses have developed unique relationships with the organisms that transmit them from plant to plant. Generally, one type of virus is transmitted by one type of vector. For example, the Nepovirus genera of viruses are transmitted only by nematodes in the genera Xiphinema and Longidorus in the nematode family Longidoridae and not by other nematodes or other virus vectors such as aphids, beetles, and whiteflies. The interaction between plant viruses and their vectors ranges from a superficial and short-lived attachment to vector mouthparts to a very intimate, long-term interaction in which the virus replicates within the cells of the vector.

The length of time required for a vector to acquire virus from an infected plant and the time that a vector continues to transmit the virus to healthy plants are determined by the interaction between the virus, the plant, and the vector. For example, the aphid-transmitted Potyviruses are attached superficially to the aphid stylet, and the virus is acquired and released within minutes during short feeding probes when the aphid inserts the stylet through the plant cuticle into the cytoplasm of epidermal leaf cells. In contrast, the aphid-transmitted Luteoviruses require several days for transmission. Luteoviruses are acquired by aphids during extended feeding periods from the phloem of the plant (these viruses only multiply in the phloem of infected plants) and can be transmitted to healthy plants only after the ingested virus moves through the gut wall of the aphid into the circulatory system and then from the circulatory system into the salivary glands from which the virus is transmitted in the saliva during feeding. Several Rhabdoviruses replicate in their aphid vectors after they are acquired during feeding, and the aphids transmit the virus for the rest of their lives. These examples of the types of interactions between aphid-transmitted plant viruses and their aphid vectors illustrate the wide variety of associations that can occur between vectors and the viruses they transmit.

**TRANSMISSION THROUGH VEGETATIVE PROPAGATION AND GRAFTING**

Many horticultural crops are propagated vegetatively, and this results in a very efficient method of virus spread through the use of tubers, runners, cuttings, corms, and bulbs from virus-infected plants. Virus spreads to nearly all organs and tissues of an infected plant, and vegetative propagation from plant parts gives rise to infected plants without the need to establish infection in a new plant.

Grafting of a plant part from one plant onto a different plant to produce a new plant with characteristics of both is a common horticultural practice that is employed to take advantage of the desirable characteristics of the parent plants. For example, many commercial apple and grape plants have roots derived from selected plants and shoots that are from a different plant. If one part of the grafted plant contains virus, the virus usually moves into the healthy part of the plant and establishes infection. Management of virus diseases in vegetatively propagated crops or crop plants that are produced by grafting is accomplished by regulatory schemes for the establishment and maintenance of virus-free “mother” plants that are used as the source for plant production.

**CONCLUSION**

As discussed in this article, there are many possible routes through which a plant may become infected with a virus. Development of effective management strategies for plant diseases caused by viruses often depends on identifying and understanding all the means by which a particular virus is introduced into a plant host.

INTRODUCTION
The structure of coat protein (CP) had been thought to protect its infectious genome from the adverse conditions of the intra- and extracellular milieu. Advances made possible by recombinant DNA technologies have established that the viral CP is multifunctional and, most important, that the architecture of mature virions is critical for the survival of the virus, insect transmission, and disease. Knowledge of virion structure is an important prerequisite for understanding the overall biology of plant viruses. One way to elucidate the final structure of stable virions is to dissect the assembly process through in vitro and in vivo studies.

INTERACTIONS PROMOTING VIRUS ASSEMBLY
The assembly of mature virions, which involves nucleic acid–protein interactions, is an important phase in the virus life cycle. This process has been shown to be obligatory for several plant viruses to move from cell to cell, be transported over long distances within a plant through the phloem, and be acquired by insect vectors for dissemination to new hosts. The following interactions involving protein and RNA influence the assembly process: 1) Protein–protein interactions play a major role in virion assembly, although their contribution relative to RNA–protein interactions varies among different plant virus groups (e.g., Tymovirus and Comovirus virions are predominantly stabilized by protein–protein interactions and can therefore form empty capsid shells without the cognate genomic RNA); 2) RNA–protein interactions predominate in guiding the assembly for viruses such as Tobamoviruses, Alfamoviruses, and Bromoviruses. In these viruses capsid formation requires RNA and empty virions are therefore not formed in vivo; 3) Sequence-independent RNA–protein interactions are typically theorized as stabilizing encapsidated RNAs. Basic N-terminal arms found in the CPs of several RNA viruses are implicated in the interaction with RNA phosphates, facilitating the assembly of infectious virions; 4) Finally, sequence-dependent RNA–protein interactions are often critical in initiating the viral assembly process. Because viral RNA and CP subunits are localized in the same compartment of the cell as cellular tRNA, mRNAs, or rRNA, these species could potentially be copackaged with viral genomic RNAs. Specific sequence and structure–dependent interactions between RNA and CP are thought to ensure that the majority of assembled virions exclusively contain viral RNA.

PATHWAYS
Tobacco mosaic tobamovirus (TMV) is a helical plant virus in which assembly is initiated by specific interaction between a disk of structural protein subunits and an internal sequence in the RNA genome (Fig. 1A). The study of virus assembly using TMV was pioneered by Frankel-Conrat, who reconstituted TMV particles in vitro from dissociated protein and RNA.

The first experimental evidence that purified RNA and CP of an icosahedral virus (Cowpea chlorotic mottle virus, CCMV, a species in the Bromovirus genus) can reassemble in vitro to produce infectious particles was provided as early as 1967 by Bancroft and Hiebert. Bromovirus virions are predominantly stabilized by RNA–protein interactions; RNA is therefore required for the formation of icosahedral capsids in vivo. RNA–protein interactions are thought to neutralize the negative charge of the RNA and allow condensation of the nucleic acid within the virus particle. The assembly process is independent of the virus replication complex; there is no indication of the involvement of any other virus-encoded proteins. Bromoviruses assemble into icosahedral particles with $T=3$ quasisymmetry (Fig. 1B). The structure of CCMV has been determined by X-ray crystallography to have 3.3 Å resolution. Based on polymerization kinetics observed by light scattering and gel filtration assays, it has been suggested that capsid assembly in CCMV is nucleated by the formation of a pentamer of dimmers. Recent in vitro assembly studies with brome mosaic virus (BMV), the prototype Bromovirus, indicated that assembly of infectious virions requires a highly conserved 3′ terminal tRNA-like structure (TLS). The transient yet critical involvement of the TLS or tRNAs in BMV assembly suggests a role in the formation of CP dimers that serve as intermediaries in the encapsidation pathway.
Genome packaging is considered to be a highly specific process. During packaging, viral nucleic acids must be distinguished from other cellular RNA molecules present in the compartment in which assembly takes place. Such discrimination is thought to result from specific recognition of sequences or structures unique to viral nucleic acids, termed origin of assembly sequences (OAS) or packaging signals. These signals are often represented by small stretches of RNA that fold into unique secondary or tertiary structures specifically recognized only by the cognate CP. Although these specific sequences might promote packaging of viral genomic RNAs, their presence does not guarantee packaging, because several other parameters also govern the encapsidation process. For example, the fixed dimensions of icosahedral capsids impose an upper limit on the size of viral nucleic acid that can be accommodated. Consequently, nucleic acids substantially larger than a wild-type genome cannot be packaged, even if appropriate packaging signals are present. In contrast to viruses having one genomic segment (e.g., TMV, TCV, SBMV), those with a genome divided among multiple nucleic acid species have evolved mechanism(s) to balance distribution of the genome segments into either a single virion or among multiple virions. The genomes of plant viruses belonging to the Bromo (icosahedral), Cucumo- (icosahedral), Hordei- (rigid rods), and Alfamoviruses (bacilliform) genera are divided among three RNA segments. In each of these genera, the genomic and subgenomic RNAs are distributed into separate particles, and their size and the number vary with genera. For example, in bromo- and cucumoviruses, the largest two genomic RNAs are packaged individually into two virions and the third genomic RNA and its subgenomic RNA are hypothesized to copackage into a third virion (Fig. 1C).[8] These virions do not display any physical heterogeneity in either size or appearance. In hordei-viruses, the three genomic RNAs are encapsidated into three distinct-sized rods. Whether the subgenomic is packaged or not is unknown because of its low concentration. In members of the genus Alfamovirus, the three genomic RNAs and the subgenomic RNA are packaged individually into four distinctly sized virions, and the mechanism(s) involved in maintaining a high degree of precision in distributing the four RNAs into three or four individual capsids is currently obscure.

**WHY STUDY VIRUS STRUCTURE?**

Structural information on viruses has provided inspiration for many novel approaches in biology, such as development of viruses as epitope carriers for gene therapy and for nanoengineering of materials. Two RNA plant viruses—TMV and cowpea mosaic virus (CPMV)—accumulate in very high concentrations in their hosts, and large quantities of highly purified virions can be obtained in less than 48 hours. Because the CP structure of these two viruses is known in detail, they have been used as vectors for the insertion and presentation of foreign peptides on the virion surface.[9,10]
The structure of a given virus must be flexible enough to disassemble in order to release its contents upon entry to a healthy host cell. Structural transitions are therefore thought to occur for many virions due to defined chemical switches resulting in unique gating mechanisms that control the containment and release of the contents. Thus, knowledge gained from understanding the principles of the architecture has helped in using viruses as protein cages for material synthesis and molecular entrapment.\textsuperscript{10,11}\textsuperscript{10,11}

Finally, structure has been implicated in playing an important role in controlling many virus–host interactions. In several viruses, experimental evidence has indicated that virion structure assembled from mutated CP subunits has failed to optimally interact with host machinery, resulting in defective local and long-distance movement, and in altered symptom expression in susceptible hosts.

**CONCLUSION**

Despite many advances, knowledge of the mechanism by which plant viruses package their genomes is still in its infancy. Most of the progress in this direction is limited to viruses containing RNA genomes rather than DNA genomes. Understanding assembly and disassembly mechanisms will likely shed light on the development of novel strategies for virus disease control.

INTRODUCTION

Initiation of plant virus infection is a complex process involving the entry and disassembly of the virus particle. Specifically, a virus particle must remain stable within the extracellular environment to protect its genome. However, upon entry into a host cell the particle must destabilize and disassemble in order to initiate the infection process. The mechanisms responsible for shifting particle stability in response to changing environmental conditions have been identified for a number of plant viruses. Furthermore, methods to prevent disassembly have been investigated as a means to develop disease resistance. In this article, the processes that contribute to the initiation of a plant viral infection will be discussed.

VIRUS ENTRY

Unlike animal viruses, which utilize cell surface receptors to gain entry into a cell, plant viruses typically gain access to a new host via nondestructive cellular wounds that penetrate the cell wall and plasmamembrane.[1] Wounding and subsequent infection can occur by mechanical means; for example, through wind-driven rubbing of infected on healthy plants or by damage from contaminated farm implements. Although not of major economic importance, mechanical transmission using some type of abrasive, such as carborundum or celite, has been an important experimental method used in the study of numerous plant viruses. In comparison to mechanical transmission, the majority of economically important plant viruses are vector transmitted. Invertebrates that feed by sucking on plants, for example, aphids and whiteflies, make up the majority of plant virus vectors. However, other invertebrates such as nematodes and beetles as well as fungi—including members in the genera Olpidium and Polymyxa—also are capable of vectoring plant viruses. Generally, interactions between viruses and their vectors are highly specific, with a vector species transmitting only specific types of viruses.[1] However, all of these vectors provide a direct method of entry for the virus into the cell cytoplasm.

VIRUS DISSASSEMBLY

In general, virus particles are stable macromolecules that function to protect their genomes from degradation. However, once inside a cell, the virus particle must disassemble in order to initiate virus replication and spread. Cellular entry therefore requires the normally stable virus particle to destabilize to permit the virus genome access to the host’s molecular machinery. The process of switching from a stable to an unstable particle requires a sophisticated mechanism for sensing changes in the surrounding environment. For many viruses this switching mechanism is thought to involve clusters of negatively charged carboxylate groups that reside at the interfaces between adjacent coat protein subunits (Fig. 1).[2] In the extracellular environment, the repulsive negative charges of the carboxylate groups are neutralized by divalent cations (such as Ca++) or protons. However, upon entry into a cell the lower concentration of cations and the higher pH of the surrounding environment result in the loss of stabilizing cations and protons, allowing the negatively charged carboxylate groups to directly interact. The repulsive electrostatic charges of these groups then function to destabilize the virus particle.

For rod-shaped viruses such as Tobacco mosaic virus (TMV), the role of interacting carboxylate residues has been well studied. For each of the approximately 2140 coat protein subunits that make up a TMV particle, there are three known carboxylate groups: one interacting axially, one interacting laterally, and one interacting between the coat protein and the viral RNA (Fig. 1).[3] All of these interacting carboxylate groups have a role in controlling the stability of the TMV particle.[4] Interestingly, destabilization does not happen evenly along the axis of the rod-shaped TMV particle, but occurs predominantly at the 5’ end of viral RNA. The polar nature of virion disassembly is due to instabilities in interactions between the TMV coat protein and the viral RNA. Each TMV coat protein binds three nucleotides of the viral RNA with the strongest binding occurring when a guanine residue is present in the third position.[3] Although there is a preponderance of guanine residues in the third position throughout the viral genome, there are none in the 5’ leader sequence of the viral RNA. This added instability,
along with the repulsive interactions derived from the carboxylate groups, leads to the loss of coat protein subunits from the 5’ end of the viral RNA.

The repulsive interactions of carboxylate groups identified within icosahedral viruses such as *Cowpea chlorotic mottle virus* (CCMV) have been shown to control particle swelling. [5] Particle swelling by as much as 10–15% has been postulated to open channels that allow the release of the viral genome. However, swelling of the virus particle by itself does not always correlate with disassembly because a CCMV mutant deficient in virion swelling readily disassembles in vivo. [6] In addition, some other icosahedral viruses, such as *Cucumber mosaic virus*, do not display particle swelling. [5]

Based on these and other findings, it has been proposed that the N termini of CCMV coat proteins, located at the pentameric vertices of the virus particle, undergo a major structural transition from the interior to the exterior of the virus particle. [6] This structural transition likely provides a channel for the release of the viral RNA into the cellular environment. Interestingly, this structural transition is still induced by changes in pH and cation concentration, factors that suggest the involvement of a carboxylate interaction.

**TRANSLATION- AND REPLICASE-MEDIATED DISASSEMBLY**

Instability mediated by carboxylate interactions does not result in the complete disassembly of either icosahedral or rod-shaped viruses. Instead, the induced instability results in the partial release of the viral genome. For viruses with positive-strand RNA genomes such as TMV and CCMV, this leads to the exposure of ribosome binding sites on the genomic RNA and results in the initiation of protein translation. Ribosome translocation along the length of the genomic RNA results in the removal of the viral RNA from the remaining coat protein/virus particle. The linking of disassembly with translation of the viral genome has been termed cotranslational disassembly, and has the advantage of allowing the viral RNA to remain protected in the cytoplasm until replication is initiated. [7] A similar process, termed replicase-mediated disassembly, also may contribute to the uncoating of the virus particle. [8] For TMV, genome binding and transcription by the viral replicase proteins appear to result in the removal of coat protein subunits from the 3’ non-translated region of the genomic RNA. Thus, complete disassembly of an RNA viral genome may involve both
translation- and replicase-mediated removal of coat protein subunits from the viral RNA.

CROSS PROTECTION: DISRUPTING VIRUS DISASSEMBLY

Cross-protection, defined as the ability of one virus to prevent or delay the infection of a subsequent virus, has been studied as a means to generate novel forms of virus resistance. More recently, plant transformation technologies have significantly expanded our abilities to investigate this phenomenon. In general, cross-protection mechanisms have been linked to either RNA-mediated mechanisms—such as the activation of host-derived genesilencing—or to protein-mediated mechanisms that disrupt the virus life cycle. The coat protein of TMV has been shown conclusively to play a role in conferring protection in both classical cross-protection and transgenic coat protein-mediated resistance. [9] Specifically, studies have demonstrated that protection can be overcome using infectious uncoated viral RNA as inoculum. Structural studies have also demonstrated that protection is dependent upon the capability of the protecting TMV coat protein to bind the viral RNA and assemble into a virus particle. [10] Mutant coat proteins deficient in assembly cannot confer protection. More important, coat proteins with enhanced abilities to assemble significantly enhance observed levels of protection. [9,10] Together these findings support a recoating protection model in which the presence of the protecting coat protein functions to block the disassembly of the infecting virus particle.

CONCLUSION

The ability of a plant virus to initiate an infection clearly is dependent upon a complex set of mechanisms. These mechanisms also may affect virus movement, disease development, and host resistance. [9] For example, TMV moves systemically within its host’s vascular tissues as an assembled virus particle; hence, upon exiting the vascular tissues the virus particle must undergo disassembly in order to initiate a systemic infection. Thus, understanding the processes involved in the initiation of a plant virus infection will enhance our overall knowledge of the entire infection process. Unfortunately, for most viruses our understanding of these processes is minimal. One major limitation is the lack of structural information available for the majority of plant viruses. Thus, there is a need for more information regarding the structure and function of virus particles during the infection process.

INTRODUCTION

Nonmotile organisms such as plants require a high plasticity in their developmental programs to changing environmental conditions. In general, developmental pathways of plants are more flexible than those of animals because of the continuous production of new meristems. Roots display a wide array of adaptations to spatial and temporal fluctuations in the availability of edaphic resources, resulting in changes in growth rate, diameter, growth angle, the formation of adventitious roots, and anatomical acclimations such as the formation of apoplastic barriers or aerenchyma. The availability of nitrate, phosphate, sulfate, iron, and even micronutrients such as zinc and manganese can dramatically alter the development of the root system. This article is restricted to those changes that have attracted the most interest during the last decade: the development of lateral roots and the differentiation of epidermal cells in response to the availability of nitrate, phosphate, and iron. Transgenic and genetic approaches have allowed to discover the first components that come into play when the availability of or the demand for nutrients necessitates changes in the developmental program. Recent progress concerning the signaling pathways that control these changes is considered as a further aspect.

LATERAL ROOTS

The formation of lateral roots can dramatically change the architecture of the root system, leading, in general, to an increase in the volume of soil that is explored by the plant. This process shows high plasticity and is responsive to the environment, both being determined by developmental programs and external signals. Lateral roots are initiated in an acropetal sequence from the outermost layer of the stele, the pericycle, in the differentiation zone of the parent root. Pericycle cells opposite to the xylem poles are primed for the formation of laterals, as indicated by a separately regulated cell cycle. A dome-like structure of already differentiated cells is formed by sequential periclinal divisions. Some of these cells form an active meristem that start to function as initials after the primordium has emerged from the parent root, a process driven by cell expansion rather than cell division. The anatomy of lateral and primary roots is highly similar, suggesting that embryonic and postembryonic root developments share some common mechanisms. This is supported by some, but not all, root developmental mutants, indicating that, besides some general similarities in the development, aspects in the organization differ between both root types.

The number and placement of lateral root primordia along the main axis are strongly affected by environmental signals, particularly by the availability and distribution of nitrate and phosphate. In general, high nitrate and phosphate levels suppress the development of lateral roots, while low concentrations of these nutrients favor lateral root growth. When plants were grown at low nitrate or phosphate levels, local nutrient-rich spots led to localized proliferation of lateral roots. Thus both local and systemic signals are integrated to allow for efficient foraging of limited resources. Depending on species and growth conditions, the effect of nitrate is either to elongate or both to initiate and elongate lateral roots. While the response to nitrate is primarily advantageous in relation to interspecies competition, the increase in lateral root elongation triggered by P is thought to enhance phosphate acquisition in addition to increasing competitive strength.

CLUSTER ROOTS: A SPECIAL CASE

Some terrestrial vascular sporophytes produce tight groupings of determinate lateral roots in a small region of the parent root, referred to as cluster roots or proteoid roots. These closely spaced laterals form a bottlebrush-like cluster and emerge synchronously on the same plant (Ref. [5], Fig. 1). Similar to ordinary lateral roots, rootlet primordia arise from the pericycle. Within the cluster, rootlets emerge opposite every protoxylem pole, leading to the typical structure of cluster roots. In some species, a rootlet can become the axis for another cluster, resulting
in complex clusters. The development of cluster roots is followed by an exudative burst, during which a disparate array of root exudates is released into the rhizosphere, facilitating the mobilization and diffusion of nutrients, mainly P and Fe.\(^5\) The development of the morphological structures appears to be separately regulated from the export of organic acids. The number of root clusters is greatly enhanced by P starvation. The formation of cluster roots is suppressed by a high P status, indicating that their development is controlled by internal signals and not by the local presence of phosphate.\(^6\) Because cluster roots are formed by nonmycorrhizal species or those with reduced mycorrhizal infection, cluster roots are thought to provide an alternative means to mycorrhiza in phosphate acquisition. Some species form cluster roots in response to Fe deficiency, both responses being mutually exclusive in most cases.\(^5\)

**ROOT HAIRS**

Root hairs are fast-growing extensions of epidermal cells which function in the uptake of water and nutrients and are important for microbe interactions. Similar to lateral roots, root hairs reach a predictable length and greatly increase the surface area of the root. The formation of root hairs does not occur in all species, indicating that root hairs are not essential for the functions listed above. The development of root hairs can be divided into three stages: specification, initiation, and elongation. A large number of genes that control the development of root hairs have been identified by molecular genetic studies, mainly in *Arabidopsis thaliana*\(^7\). Determination of the cell fate in hair cells (trichoblasts) and nonhair cells (atrichoblasts) is controlled by a transcription factor cascade, which interacts in a complex manner to produce the epidermal patterning typical of *Arabidopsis*. Initiation of root hair growth starts with cell expansion in a small, disc-shaped area and the induction of expansins that catalyze wall loosening. During tip growth, new cell wall material is secreted to the cell tip and cytoskeletal elements accumulate at the tip. The direction of tip growth is controlled by a calcium gradient, GTP-binding proteins from the Rop family and microtubules. Pharmacological and genetic studies indicate that the plant hormones ethylene and auxin are involved in epidermal cell specification and elongation, acting parallel to or downstream of the cell specification genes, although the role of the hormones in cell specification is not unambiguous.

In the aging primary root and in laterals, cellular patterning can be modulated by environmental factors, mainly by the availability of phosphate and iron. Phosphate deficiency increases both the length and the density of root hairs (Fig. 2), leading to a decrease in a
P-depleted zone around the roots that develops rapidly during phosphate uptake because of the low solubility of phosphate in the soil solution. Under iron shortage, in dicots and nongrass monocots, root hair proliferation is associated with a suite of adaptive processes which helps to acquire iron from sparingly soluble sources. Suboptimal Fe availability increases the density, but not the length of root hairs. In Arabidopsis, hairs that are formed in response to nutrient shortage are both in the normal position and in positions that are normally occupied by nonhair cells, indicating postembryonic changes in epidermal patterning.

In addition to root hair formation, root epidermal cells can undergo ultrastructural changes that are presumably important for nutrient acquisition. In response to phosphate and iron shortage, some cells in the zone of metaxylem differentiation develop into transfer cells, characterized by polarized wall ingrowths which are primarily located on outer tangential walls. The enlargement of the plasma membrane surface, which is associated with the development of this cell wall labyrinth, is thought to increase the flux of solutes between the rhizosphere and the symplast. The presence of numerous mitochondria and other organelles, in particular Golgi and endoplasmic reticulum, is typical of transfer cells, suggesting a high energy requirement. The physiological function of transfer cells is not yet clear, but from their spatial and temporal pattern, there appears to be justification for a function in the acquisition of iron and phosphate.

**SENSING AND SIGNALING**

Little is known about how information from the environment is sensed and transduced to downstream targets, and how these pathways converge with developmental control. Sensing of nutrient levels appears to be complex, involving (at least) two distinct signaling mechanisms: a systemic circuit integrating information of the nutritional status from different plant parts, and a second, local system that perceives the level of nutrients in the vicinity of the roots. An example for the latter type is the development of root hairs and rhizodermal transfer cells, which are not, or only in part, affected by the overall nutrient status of the shoot, dissimilar to homeostatic compensation of the nutritional levels by physiological responses which is systemically regulated. In contrast, the formation of cluster roots is mainly linked to the whole plant nutrient level and probably regulated by a long-distance signal generated in the shoot.

Nutrient sensors involved in changes in root development have not yet been identified. The nitrate transporter AtNRT1.1 (CHL1) may play a role in nitrate sensing besides its function in nitrate uptake. At low nitrate levels and low pH, chl1 mutants show reduced growth of lateral root primordia, suggesting that the CHL1 product is required for lateral root maturation. A further component in the signaling pathway leading to localized proliferation of lateral roots is the MADS box transcription factor ANR1. Transgenic plants with low levels of ANR1 message lack the ability to respond to localized nitrate. Whether the level of nutrients is monitored by external sensor(s) facing the apoplast or after absorption by the plant remains to be elucidated. Nitrate does not need to be assimilated to induce meristematic activity in lateral roots, suggesting that plants are able to sense external nitrate. This might also be true for other nutrients. Several genes with putative function in signal transduction have been found to respond within hours to phosphate, potassium, and iron deficiencies, which are unlikely to be associated with significant changes in nutrient concentrations, supporting the assumption that plants can sense changes in the availability of nutrients in close proximity to the roots.

Auxin appears to be a key regulator in lateral root development. Application of auxin results in increased initiation of lateral roots, and an auxin-overproducing mutant in Arabidopsis forms lateral roots in high density. The direct participation of auxin in phosphate- and nitrate-induced changes in root development has, however, not been proven unequivocally. Free auxin levels are higher in phosphate-starved plants, but auxin mutants were shown to respond like the wild type to changes in phosphate availability. Transfer cells are induced by auxin, but mutants with reduced auxin or ethylene sensitivity showed no significant reduction in transfer cell frequency, questioning a primary role of hormones in their induction. More unambiguous information is available for the development of root hairs. Whereas functional products of genes involved in ethylene and auxin signaling are required for the development of iron stress-induced hairs, both hormones appear to play no direct role in the formation of hairs induced by phosphate deficiency, indicating separate regulation.

Pollen-Stigma Interactions

Simon J. Hiscock
University of Bristol, Bristol, U.K.

INTRODUCTION

The pollen-stigma interaction, as defined by Heslop-Harrison, consists of: 1) pollen capture; 2) pollen adhesion; 3) pollen hydration; 4) pollen germination; and 5) pollen tube penetration of the stigma. Successful completion of these events normally results in pollen tube growth to the ovary, leading to fertilization unless incompatibility/incongruity factors preclude. The pollen-stigma interaction is thus a necessary prezygotic courtship between the male gametophyte and the maternal tissues of the sporophyte. Molecules regulating the interaction reside at the surfaces of pollen and stigma (self-incompatibility proteins excluded), but our knowledge of their identity remains largely fragmentary.

THE STIGMA SURFACE

Stigmas can be broadly classified as wet or dry, depending on whether or not they possess a surface secretion.[1,2] Such a classification is useful in the context of this review because the nature of the pollen-stigma interaction depends largely on the microecology of the stigma.[2] For wet stigma species, investigations have focused largely on species from the Solanaceae (notably Nicotiana), whereas for dry stigma species, Brassica and Arabidopsis define the model.

POLLEN-STIGMA INTERACTIONS IN SPECIES WITH WET STIGMAS

Secretions on wet stigmas are primarily lipid-rich (e.g., Solanaceae) or primarily carbohydrate-rich (e.g., Lilia-ceae) and are clearly important for pollen capture and adhesion. This is because, on making contact with a wet stigma, pollen is quickly trapped and immersed within it. In Nicotiana, the absence of a stigmatic secretion results in aberrant pollen development on the stigma, preventing fertilization. Lipids have been shown to be the essential component of the stigmatic secretion necessary for pollen tube penetration because ablated stigmas of female-sterile Nicotiana can be restored to full fertility by the application of a range of lipids, particularly cis-unsaturated triacylglycerides.[3,4] Lipids within the secretion also appear to direct pollen tube growth toward the stigma by providing an increasing gradient of water potential between the desiccated pollen grain and the turgid cells of the stigma. In vitro simulations of the stigmatic environment using oil-in-water emulsions confirmed that Nicotiana pollen tubes grow down gradients of water potential toward an aqueous phase.[4] Whether the carbohydrates in lily-type secretions play a similar role in guidance and penetration of pollen tubes remains to be determined. Wet stigma species usually lack a stigmatic cuticle, so once the pollen tube has germinated and begun to grow toward the stigma, its entry and passage into the transmitting tissue are largely unimpeded. Within the transmitting tissue, chemical cues—notably TTS (a Transmitting Tissue-Specific arabinogalactan glycoprotein)—may guide pollen tubes toward the ovules; physical cues such as cell surfaces may also guide pollen tubes toward ovules.[4,5] It is also within the transmitting tissues of the style that pollen tubes of the self-incompatible (SI) members of the Solanaceae are inhibited by the action of style-specific S-RNases.[5]

POLLEN-STIGMA INTERACTIONS IN SPECIES WITH DRY STIGMAS

For nearly thirty years, Brassica has been the model for studies of pollen-stigma interactions on the dry stigma. In Brassica, studies of the default state of (compatible) pollen-stigma interactions have been combined with studies of sporophytic self-incompatibility (SSI) because incompatible pollen is recognized and rejected at the stigma surface. More recently, studies of compatibility have shifted to the Arabidopsis model.

The stigma of Brassica and Arabidopsis consists of a dome of epidermal papillae covered by a continuous cuticle that forms a major barrier to pollen tube penetration. Upon the cuticle sits a thin membrane-like layer of protein, the pellicle, which forms the first site of molecular contact between the stigma and alighting pollen grains (Fig. 1). The protein composition of the pellicle has yet to be determined, but cytological studies have revealed the presence of esterases and glycoproteins.[1,2]
In the absence of a sticky stigmatic secretion, adhesion of pollen to the stigma appears to be largely a function of the pollen wall. Structural studies in *Brassica* suggested that the lipidic pollen coating mediates adhesion because immediately after making contact with the stigma, pollen coating is extruded from the exine onto the surface of the stigma where it forms an appresoria-like “foot”[6] (Fig. 2). Nevertheless, pollen adhesion assays using the *Arabidopsis* mutant cer6-2, which fails to produce a pollen coating, did not indicate loss of adhesion in the coatless pollen.[7] This observation points to the sporopollenin exine as being responsible for pollen adhesion. Indeed, *Arabidopsis* lap (less adherent pollen) mutants, compromised in pollen adhesion, show aberrant patterns of exine development.[7] The adhesive function of the exine could be attributable to the exinic outer layer (EOL)—a thin surface layer surrounding the exine, which, like the stigmatic pellicle, has yet to be characterized.[6] Interestingly, structural studies in *Brassica* suggest that upon contact, the EOL and pellicle fuse (S. J. Hiscock unpublished observation).

Two stigmatic members of the *Brassica* *S* gene family have been implicated in pollen adhesion. Gene knockouts of *SLR1* (*S* Locus Related glycoprotein 1) resulted in reduced adhesion of pollen on transgenic stigmas, and pretreatment of stigmas with antisera to SLR1 or SLG (*S* Locus Glycoprotein) also resulted in reduced pollen adhesion.[8] Importantly, SLR1 and SLG each bind specific members of a group of pollen coat proteins (PCPs)—an interaction that may contribute to the adhesive effects of SLR1 and SLG on pollen.

The main role of the pollen coating appears to be in pollen hydration, because all *Arabidopsis* cer mutants are defective in pollen hydration and consequently do not produce a pollen tube on the stigma. Mutant cer6-2 pollen, which has virtually no pollen coating, cannot stimulate water release from the stigma but germinates readily in liquid medium in vitro, and under high humidity in vivo. All cer mutants (cer1, cer3, cer6, and pop1) are unable to synthesize long-chain lipids.[5,7] The fact that cer mutants can be rescued by application of triacylglycerides suggests that lipids in the pollen coating play a role in pollen development similar to the lipids in the stigmatic secretions of *Nicotiana*.[3,7] Lipids within the pollen foot may set up a gradient of water potential between the pollen grain and the stigma that acts as a guide to the growing pollen tube, indicating the direction of the stigma. In support of this assertion, pollen tubes of *Brassica* always grow through the pollen foot prior to penetration of the stigma.[6]

Regulated hydration of pollen is clearly essential for normal pollen development on stigmas of *Brassica* and *Arabidopsis*, but pollen coat proteins (in addition to lipids) appear to play a key role in this process. GRP17 is an oleosin-domain protein present in *Arabidopsis* pollen coating that is necessary for normal hydration of the pollen grain. GRP17 belongs to a family of oleosin-domain *Arabidopsis* pollen coat proteins, orthologues of which are also present in the pollen coating of *Brassica*. It has been suggested that this variable group of oleosin proteins and a group of similarly variable pollen coat lipases may form...

B) Transmission electron micrograph (TEM) of oblique section through cell wall of stigmatic papilla stained with *z*-naphthyl acetate and hexazatized pararosanalin to visualize esterase activity of the pellicle (P). Bar = 0.2 μm.

Fig. 2 The *Brassica* pollen foot. TEM of oblique section through pollen-stigma interface 1 hour after compatible pollination. P = pollen grain, Ft = pollen foot, S = stigmatic papilla. Bar = 2 μm.
CONCLUSION

As more is becoming known about the molecular mechanisms of SI, interest is focusing on molecules that mediate the default state of the pollen-stigma interaction—compatibility. The importance of lipids on the stigma in early pollen development is becoming clear, and insight into pollen adhesion and hydration is being gained through studies of Arabidopsis male-sterile mutants. Further insight will follow as more subtle screens are devised for Arabidopsis mutants compromised at various stages of the pollen-stigma interaction. Key mutants will be those that show penetration defects, possibly resulting from lesions in pollen genes that encode enzymes such as cutinase. Another key challenge will be to identify and functionally characterize the proteins that constitute the pellicle of dry stigmas.

Polyploidy

Jan Dvorak
University of California, Davis, California, U.S.A.

INTRODUCTION

Polyploid organisms contain more than two genomes. The gametophytic (haploid) chromosome number is \( n \), and the sporophytic (somatic) chromosome number is \( 2n \). The basic chromosome number in a phylogenetic lineage is \( x \). Both \( n \) and \( x \) should be presented to describe ploidy unequivocally. For example, \( 2n = 4x = 40 \) indicates that chromosome number is being described in a sporophyte that is tetraploid and has 40 chromosomes.

TYPES OF POLYPLOIDY

Two basic types of polyploidy are recognized: autoploidy (autoploidy) and allopolyploidy (allopolyploidy). They are defined according to either the origin of a polyploid or its meiotic chromosome behavior. According to the former definition, autoploids are of an intraspecific origin, whereas allopoloids are of a hybrid origin. According to the latter definition, autoploids show multivalents at MI of meiosis and polysomic inheritance, whereas allopoloids show bivalents at MI and disomic inheritance. The term segmental allopolyploidy,\(^1\) proposed for intermediate states between autoploidy and allopolyploidy, is inappropriate in most cases and should not be used.\(^2\)

The genomic constitution of polyploids is expressed by formulas in which genomes are designated by capital letters according to their relatedness (Table 1). An autotetraploid may have a formula AAAA, reflecting the fact that its genomes originated from within a single species. Its chromosomes are homologous and it likely shows polysomic inheritance. In contrast, an allotetraploid may have a formula AABB, reflecting the fact that its genomes were contributed by two different species, one contributing the A genomes and the other contributing the B genomes. The corresponding chromosomes in the A and B genomes are very likely homeologous and the species likely shows disomic inheritance.

The sources of genomes are identified by genome analysis of the polyploid.\(^3\) Description of various methods of genome analysis can be found in a compendium on this subject.\(^4\) In its classical form, it consists of analyses of chromosome pairing at MI in hybrids from crosses between a polyploid and its relatives.\(^5\) Sharing of isozyme alleles—chloroplast genome restriction fragments and nucleotide sequences—and restriction fragments of nuclear repeated nucleotide sequences—in situ hybridization of labeled heterologous genomic DNA—can provide additional valuable information on the origin of polyploid species. Once a diploid species (or its closest extant relative) that was the source of a genome in a polyploid is identified, the same letter is assigned to that genome in the polyploid and the diploid (Table 1). Genome evolution that may have occurred since the origin of a polyploid, extinction of a diploid ancestor, or hybridization may result in failure to find a diploid whose genome fully fits a genome of a polyploid. An imperfect fit between genomes is indicated by assigning superscripts or subscripts to genome designations or by other notation in genome formulas.

GENETIC TRANSMISSION

Polyploidy greatly impacts gene segregation. In an autotetraploid, three heterozygous states—simpex (Aaaa), duplex (AAaa), and triplex (AAAa)—are possible in addition to the two homozygous states, nulliplex (aaaa) and quadruplex (AAAA). Additionally, there is an opportunity for double reduction if a crossover occurs between the locus and centromere. Double reduction creates an opportunity for sister alleles getting into a gamete instead of homologous alleles. The maximum equational segregations of a duplex heterozygote AAaa (A being completely dominant over a) is 19.5 dominant phenotypes:1 recessive phenotype, as compared to the 35 dominant phenotypes:1 recessive phenotype for strictly reductional segregation of the duplex.\(^5\)

In an allotetraploid, a chromosome can pair during meiosis either homogeneticaly, i.e., with its homologue (e.g., chromosome 1A pairs with 1A), or heterogenetically, i.e., with a homoeologue (e.g., chromosome 1A pairs with 1B). A vast majority of allopoloids are meiotically diploidized, meaning that only homogenetic pairing occurs. In some polyploids, heterogentic chromosome pairing is genetically suppressed. An example of a heterogenetic pairing suppressor is the wheat \( Ph1 \) locus. If the gene is mutated or removed by aneuploidy, heterogentic

meiotic pairing occurs at MI. Diploidized allotetraploids show disomic inheritance, provided that the locus duplicated in the other genome pair is homozygous recessive. If both loci are heterozygous (AaAa) and A is completely dominant over a, an allotetraploid segregates 15 dominant:1 recessive phenotypes.

INCIDENCE

Polyploidy is widespread in plants but rare in animals. Its incidence may be as high as 70% in angiosperms. It is claimed that as much as 95% of all species of homosporous ferns are polyploid, although this figure is still being
debated. The highest chromosome number and highest ploidy among plants was recorded in fern *Ophioglossum pycnostichum* 
\(2n = 84x = 1260\). In angiosperms, polyploidy is more abundant in monocots than in dicots. For example, as many as 80% of all grass species were estimated to be polyploid. Polyploidy is more abundant in herbaceous angiosperms, particularly those that are perennial, than in woody species. Polyploidy is rare in gymnosperms. For example, only 1.5% of coniferous species are polyploid.

**ORIGINS**

The principal mechanism by which natural polyploids originate is the union of an unreduced gamete with a reduced gamete or two unreduced gametes.\(^7\) The union of an unreduced diploid gamete with a reduced monoploid gamete of the same species results in an autotriploid. Autotriploids are usually highly male-sterile but partially female-fertile, and may serve as bridges in the origin of autotetraploids.\(^8\) Autotetraploids were estimated to originate with a frequency of about \(10^{-5}\).\(^8\) The frequency of unreduced gametes is greatly elevated in interspecific hybrids. Therefore, the frequency of the emergence of allopolloids is more dependent on the frequency of interspecific hybridization than on the production of unreduced gametes by the parental species. The cross-pollinating mating system enhances the incidence of allopolyploidy. Both auto- and allopolloids originating from cross-pollinating species, including those that are self-incompatible, are usually self-pollinating, which assists nascent polyploids in their propagation and establishment.

**EVOLUTIONARY SUCCESS**

Polyploids have sometimes been portrayed as genetically depauperized taxa exploiting an available habitat at the expense of long-term evolutionary success. This view is incongruous with the tendency of allopolloids to become geographically widespread. Moreover, molecular mapping has demonstrated that some apparently diploid plant lineages are actually paleopolyploid (Table 1), showing that polyploids can establish successful phylogenetic lineages. It has been demonstrated for more than 30 species that polyploids originate recurrently in natural populations.\(^9\) Recurrent origin and interpolplody hybridization, followed by introgression, broadens the polyploid gene pools and enhances the potential of polyploids to adapt to changing environment. Nascent allopolloids are notorious for their genetic and meiotic instability, caused by recombination and subsequent segregation, DNA rearrangement, and transposition, and epigenetic variation caused by differential methylation. These mechanisms increase variation in nascent polyploid populations and contribute to their adaptation and evolutionary success.

**INDUCED POLYPLOIDY**

Polyploidy can be induced by temperature shocks and numerous other treatments interfering with mitosis. The most effective is treatment with the alkaloid colchicines, which blocks entry of a mitotic cell into the anaphase. Because colchicine is always applied on multicellular tissues, treated plants become polyploid chimeras. Nitrous oxide dissolved in cytosol under pressure also blocks polymerization of microtubules and results in polyploidization. The gas can be applied at the time of zygotic division, resulting in the entire plant being polyploid. Endopolyploid cells, which are frequent in somatic tissues of plants, can also be a source of polyploids regenerating from them. Endopolyploidy is the principal cause of polyploidy of adventitious shoots and plants regenerated from tissue culture. Autotriploids can be produced by crossing diploids with autotetraploids. In some cases, this cross is difficult (triploid block) or is possible in only one direction.

**PHENOTYPIC EFFECTS**

The primary effect of autoploidy is larger cell size. Therefore, autoploids are often more robust, have thicker and darker leaves and larger stomata and pollen size, and are slower developing and less tolerant of environmental stresses than their diploid counterparts. There is often a specific ploidy level for increase in plant size due to autoploidy. Alloploids tend to be intermediate between parents, although they may resemble one of the parents in specific traits or may show altogether new traits.

**POLYPLOID CROPS**

Polyploidy was about as frequent in crops as in their noncrop relatives.\(^10\) Polyploid field crops and fruit trees, their genome formulas, and synopses of their genome analysis are listed in Table 1. The majority of polyploid crops are allopolyploid. Low fertility of triploids has been exploited in the production of seedless triploid varieties of watermelon and bananas. In sugar beet, triploid varieties are more productive than their diploid and autotetraploid counterparts, and have been commercially used to produce monogerm varieties. Some varieties of apples and cherries are triploid.
CONCLUSION

Polyploidy is an important evolutionary strategy in the plant kingdom. Many important crops are polyploid, although the incidence of polyploidy in crops does not appear to be any higher than in their noncrop immediate relatives. Polyploidy greatly modifies inheritance. In autopolyploid populations, recessive phenotypes appear in much lower frequencies than in diploid populations with similar allele frequencies. A general tendency of natural allopolyploids is to genetically “diploidize,” (i.e., to evolve bivalent meiotic chromosome pairing and disomic inheritance). The molecular and genetic mechanisms of this process remain poorly understood. Also poorly understood are gene expression and genome evolution in allopolyploid species.

University of California, Riverside, California, U.S.A.

INTRODUCTION

Genes are the fundamental hereditary units transmitted from parent to offspring in every generation. Population genetics is concerned with the statistical rules that govern the transmission of genes within collections of interbreeding individuals over time. Changes in the frequencies of genes within populations are the basis for evolutionary change, as well as the basis for the genetic improvement of plants and animals that provide human sustenance.

Population genetics employs mathematical models to describe trajectories of genetic change under various scenarios. These models are also used to design experiments to dissect the processes of evolution. The basic mathematical models of population genetics were developed long before it was established that DNA is the chemical basis of heredity. The challenge today is to analyze and learn from the rapidly accumulating body of genome sequence data. The basic models of population genetics are highly relevant to this enterprise because they are general, in the sense that change in gene frequency can be substituted with change in individual nucleotide frequency without any alteration in the underlying mathematics. This article provides a brief outline of the theory of population genetics as it applies to changes in the composition of DNA molecules over time. Several excellent books provide a comprehensive introduction to population genetics theory, including works by Hartl and Clark and Hedrick.

EVOLUTIONARY FORCES THAT DRIVE DNA SEQUENCE CHANGE

Five forces determine genetic change.[1,2] These begin with mutation, defined as a permanent heritable change in a gene. A second force is recombination, which is a randomizing force that can also lead to permanent heritable changes in a gene. Genetic random drift, defined as the small fluctuations in gene frequencies caused by the sampling of individuals in reproduction, is third. The fourth force is migration, or the movement of genes among different populations. Fifth is natural selection, in which some individuals are more successful in transmitting their genes owing to superior adaptation to their environment and hence improved survival and reproduction. Natural selection is the force that leads to adaptive genetic change; it essentially sorts among mutations to eliminate those that are deleterious and increase the frequency of those that are advantageous.

MUTATION: THE SOURCE OF GENETIC NOVELTY

Gene or nucleotide sequences are subject to constant change. To begin, mutation takes many forms, each of which has some likelihood of occurring at each DNA replication cycle. From this it is apparent that any DNA molecule is subject to mutational erosion over time; this erosion process is a form of evolutionary change. DNA sequences that code for functionally important molecules are expected to be conserved because natural selection rejects most deleterious mutational changes in functionally important genes. Current genome sequencing efforts suggest that much of the DNA of organisms does not code for proteins or regulatory signals—these regions may be evolving relatively rapidly.

GENETIC RANDOM DRIFT: THE ROLE OF CHANCE IN EVOLUTIONARY CHANGE

Once a new mutation has arisen in a single DNA molecule (to create a new allelic form of a gene or a new allele), it may be transmitted to the next generation or it may be lost. Assuming the new mutation has no effect on fitness, the probability of transmission to the next generation is $1 - [1 - 1/N]^{2N}$ in diploid organisms, where $N$ is the population size. This result follows from the fact that a new mutation will initially occur in a single individual (frequency = $1/2N$). The pool of gametes is assumed to be much larger than the $N$ reproductive individuals in the population, so sampling with replacement is appropriate. (This expression is the probability of not being lost in the first generation, derived assuming binominal sampling.) In the vast majority of cases a new mutation will be lost through the vagaries of sampling within a generation or
two. A very small proportion will drift to high frequency and be fixed (i.e., become the sole allele in the population or species).

An important result of mathematical genetics indicates that the probability of ultimate fixation of a new neutral mutation is $1/2N$ (the concept of neutrality is discussed later). Because there is a constant flux of new mutations, there will also be a constant rate of fixation of new allelic variants over the long term. In fact, the rate of fixation of new alleles is simply $\mu$, the mutation rate. This result provides a formal justification for the molecular clock hypothesis (see article on molecular evolution), because it indicates that the rate of mutational change should be constant over time if the mutation rate is constant.

A second important theoretical result from population genetics demonstrates that the average time until the fixation of a new mutation is $T \sim 4N_e$, so for large $N_e$, many mutant alleles are expected to be in transition to fixation at any point in time. ($N_e$ is a population size adjusted to take account of variation in reproductive output among different members of a breeding population.) For example, many plant species must have population sizes in the order of $10^6$ to $10^7$. The rate of mutation per nucleotide site per generation is approximately $\mu = 5 \times 10^{-9}$. If a typical gene is $10^3$ nucleotide sites in length, the total probability of a new mutation in the gene in any single generation is $5 \times 10^{-6}$. For a species size $(2N)$ of $10^6$, five new mutations in this particular gene are expected in the total species per generation. Moreover, the average new mutation that is destined to be fixed will drift in the species of size $10^6$ for 4,000,000 generations. The probability of drawing two different alleles of the gene in a population or species can be shown to be approximately

$$1 - 4N_e\mu/(1 + 4N_e\mu) = 19/21 = 0.90$$

for this numerical example, so almost every pair of genes sampled is expected to be different. Thus, high levels of molecular polymorphism are expected in species. Current efforts to define all human single nucleotide polymorphisms (SNPs) verify these theoretical predictions.

THE NEUTRALITY HYPOTHESIS: AN INTERACTION BETWEEN MUTATION AND DRIFT

The theoretical results cited in the preceding discussion are based on the assumption that selection is absent. In the 1970s, Motoo Kimura[3] and associates advanced a theory called the neutrality hypothesis that claims that a large proportion of molecular evolutionary change is neutral to natural selection. This hypothesis was in part motivated by an important calculation by J. B. S. Haldane,[4] who showed that there is an upper bound to the rate of evolutionary change under natural selection. Because selective change requires differential survival and reproduction, the reproductive excess of the species defines this upper bound. Stated differently, some or all of the reproductive excess of a species is consumed by the process of selection. Empirical evidence on rates of molecular change appear to be too high to be consistent with this upper bound, especially for long-lived low-fecundity organisms like the human. As a consequence, it was postulated that a large proportion of molecular change is not driven by selection, but by random drift and mutation.

The test of the neutral theory is to ask how well observed data fit the theoretical calculations outlined earlier. Because the neutral theory provides precise mathematical predictions, the theory is testable; moreover, these tests provide a very useful context for identifying particular genes that are selected. This is because it is known precisely how neutral genes should behave, and departures from neutrality are likely to arise from selection. To date, available data do suggest that many polymorphisms are neutral or only very weakly selected. However, the statistical power to detect departures from neutrality increases with database size, which are growing very rapidly at present.

NATURAL SELECTION: THE ENGINE OF ADAPTIVE CHANGE

Natural selection operates at the level of phenotypic differences, so an allelic change must alter some aspect of phenotype to be perceived by selection. The phenotypic dimensions of organisms, and the ways these may be perceived by various environmental factors, are very complex. These range from subtle changes in rates of flow through a metabolic pathway, to resistance to disease, to the ability to withstand extreme stress environments, to aspects of behavior, and so on. The list is virtually endless. Moreover, each aspect of phenotype may be determined by a number of different genes and by the way these genes interact in development and metabolism. It is similarly difficult to identify the precise facets of an environment that may act as a selective agent. As a consequence, selection is often identified retrospectively. That is, the analytical tools of population genetics may support the inference that selection has affected a genetic locus based on the pattern of change through time. Such an analysis rarely tells the reasons why a particular change is adaptive.

A number of mathematical results that provide useful predictions about the statics and dynamics of selective genetic change are available from population genetic theory. We will mention just one result from this large body of work. The probability of fixation of a new mutant
that is favored by selection (assuming the heterozygous genotype is intermediate in its fitness between the two homozygous genotypes) is $\sim 2s$, where $s$ is the selective intensity favoring the new mutant allele. So if $s = 0.02$ (implying a 2% selective advantage), the favored allele will still be lost 96% of the time. This result demonstrates that most new favored mutations will still be lost owing to drift.

The average time to fixation of a new favored mutant is approximately $T \sim (2s)\ln(2N_e)$ generations (where $\ln$ denotes the natural logarithmic function). Numerical iterations of this equation, compared to the neutral case, reveal that the time to fixation of selectively favored alleles is much shorter than for a neutral allele. Indeed, fixation of a selected allele can take place in orders of magnitude less time than a neutral allele. This calculation suggests that in contrast to the high levels of neutral polymorphism expected from the neutral theory outlined in the fore going, it may be relatively rare to find a selected gene in transition when one allele is favored over the other allele. The exception to this statement is the case where two or more alleles are favored, either because they lead to a higher fitness among heterozygotes or because their advantage is frequency-dependent (frequency dependent means that $s$ is not constant, but instead depends on allele frequencies). Both of these situations are referred to as balanced polymorphism. Classic examples of a balanced polymorphism are often associated with disease resistance, where the resistance allele causes some other disadvantage or where there is a constant arms race between the disease agent and the target organism favoring new mutations at a resistance locus (a case of frequency dependence). An example of such a balanced polymorphism arises from the multiple major histocompatibility polymorphism (MHC) alleles in human populations.[5] In this case, disease resistance is strongly implicated because the MHC locus is involved in the recognition of potential disease agents.

**RECOMBINATION AS BOTH RANDOMIZING AND CREATIVE FORCE**

Recombination refers to the rearrangement of genes with respect to one another on chromosomes. Recombination is a randomizing force, but it is also much more. It is a creative force that operates at many levels within plant genomes.[6] Thus, molecular evidence has revealed that recombination is responsible for the generation of many gene novelties. For example, studies of different allelic sequences of a gene often show traces of past intragenic recombination events where new allelic forms have arisen, owing to the exchange of stretches of sequence between two different alleles. This reciprocal exchange can yield a new allele that is different from both parental forms.

**THE COALESCENT: LOOKING BACKWARD IN TIME**

An important theoretical construct from population genetics is known as the coalescent. Consider a set of DNA sequences that are drawn from a single locus within a species. The sample of sequences must have all descended from a common ancestor. The point where all alleles trace back to the most recent common ancestor is known as the coalescent. It is straightforward to estimate the genealogical history of the sample by using phylogeny estimation tools (discussed in the bioinformatics article). If the nucleotide sequence diversity in the sample is the result of a drift/mutation process at equilibrium, then the arrival times of new mutation events are given by an exponential process.[7] This result provides a useful framework for testing sequence samples to see if they conform to a neutral process.

A particularly important statistic calculated from a sample of sequences is $\theta$, a measure of the nucleotide sequence diversity. A different statistic that also measures nucleotide sequence diversity is $\pi$. (Both of these quantities are related to the probability of drawing two different nucleotides at a single site averaged over all sites examined.) If we calculate $\pi$ and $\theta$ as an average over many independent replications of the evolutionary process that led to the observed sample, and if the underlying evolutionary process is the result of a drift/mutation process at equilibrium, then both $\pi$ and $\theta$ should be approximately equal to $4N_e \mu$. Thus, the difference between $\pi$ and $\theta$ should be zero under the drift/mutation assumption. A test statistic introduced by Tajima[8] based on a function of the difference between $\pi$ and $\theta$ allows one to ask whether a data set conforms to the drift/mutation assumption by testing whether this difference is zero. If the difference is nonzero, then other forces such as selection or demographic change must be invoked. Many standard computer programs for sequence analysis implement these calculations (i.e., DnaSP).

Another statistic that features importantly in coalescence theory is $T_{\text{MARCA}}$ (time to the most recent common ancestor of the sample). Mathematical calculations show that $T_{\text{MARCA}}$ is also approximately equal to $4N_e$ when the drift/mutation assumption is satisfied. Finally, if $\mu$ is known it is possible to estimate $N_e$ for the species or population from which the data came. Estimates of $N_e$ from a few important crop plants vary over nearly an order of magnitude from $2 \times 10^5$ (wild barley) to $3 \times 10^5$ (pear
millet) to $18 \times 10^5$ (maize). These data are derived from broad samples of the entire species so the estimates can be viewed as the best estimates of long-term effective population size for each species.

**MIGRATION: THE SPATIAL DIMENSION OF GENETIC CHANGE**

Every new mutation must have originated in a single individual at a specific location in space. This means that the spread of a mutation through a species is a spatial process, and it is possible to gain some insight into historical migration patterns through the analysis of geographic samples of gene sequences. Moreover, the coalescent framework has been refined to include spatial considerations, so migration rates can be quantified. Efforts to measure migration are still in very early stages, but contemporary data suggest that plants and their genes have been quite mobile over long periods of time.

There is great contemporary concern over the spread of so-called transgenes from agricultural plants into wild or weedy relatives through migration. This question has stimulated much work on the direct measurement of migration in plants. Current results suggest that gene migration rates may be higher than previously believed.

**CONCLUSION**

Although population genetics is a mature science with a history of nearly 100 years, it is more relevant today than ever. The theoretical models of population genetics provide the conceptual and statistical tools to address important questions ranging from concerns about transgene escape to detection of the influence of selection on specific genes. As the body of genome sequence data expands, these tools will become ever more important in interpreting and mining this new resource.

INTRODUCTION

Pathogens evolve. As a result of pathogen evolution, resistance genes and fungicides can rapidly lose their effectiveness in agroecosystems. To understand the processes that drive pathogen evolution, we must understand pathogen population genetics. The population genetics of all organisms is determined by interactions among five evolutionary factors: mutation, random drift, mating/reproduction system, gene flow, and natural selection. The end result of interactions among these factors is the population genetic structure of a species.

GENETIC DIVERSITY AND POPULATION GENETIC STRUCTURE

Genetic structure (often called population structure) refers to the amount and distribution of genetic diversity within and among populations. Because many pathogens have an asexual reproduction phase, pathogen genetic diversity has two components, gene diversity and genotype diversity. Gene diversity is determined by the number and frequencies of alleles at individual loci within a population. Genotype diversity is determined by the number and frequencies of genetically distinct individuals in a population. Measures of genetic diversity are especially important when considering the evolutionary potential of a pathogen population. According to Fisher’s Fundamental Theorem of Natural Selection,[1] the rate of increase in fitness of any organism is proportional to its genetic variance in fitness. In other words, pathogen populations with greater genetic diversity are expected to evolve more quickly than populations with less genetic diversity. Thus we begin to learn about pathogen population genetics and evolutionary potential by analyzing the genetic structure of pathogen populations.

THE FIVE EVOLUTIONARY FORCES

Mutation is the ultimate source of genetic variation, causing changes in the DNA sequence of a gene and creating new alleles. Mutations are rare and would not cause pathogen evolution if they operated in isolation. But when mutation is coupled with selection, mutants can increase in frequency rapidly and cause significant changes in allele frequency. Mutations from avirulence to virulence and from fungicide sensitivity to fungicide resistance are especially important in agriculture.

Population size affects the probability that mutants will be present, and also influences the diversity of genes in populations through a process called random genetic drift. Large populations have more mutants than small populations because mutation rates are relatively constant and usually quite low. Thus, large populations are expected to have greater gene diversity (more alleles) than smaller populations. Genetic drift occurs when a small random subset of a population survives a catastrophic event that causes a severe reduction in population size (a bottleneck) or when a small random subset of a pathogen population colonizes a new host population (founder event). The frequency of mutant alleles in the surviving or founding population can differ significantly from the frequency of the mutant alleles in the original population. Founder events often occur in plant pathology when a disease is introduced into a new area by accident or as a result of a breach of quarantine. Bottlenecks often occur at the end of a growing season when the crop is harvested or during a crop rotation that reduces overseeding pathogen inoculum.

Gene flow is a process in which particular alleles (genes) or individuals (genotypes) are exchanged among geographically separated populations. For strictly asexual organisms that do not recombine genes with the recipient population, entire genotypes are exchanged among populations (genotype flow). Gene flow substantially increases population size by increasing the size of the genetic neighborhood over which genes or genotypes are exchanged. Gene/genotype flow is the process that moves newly arisen virulent mutant alleles among different field populations. It is clear that the size of the genetic neighborhood is affected by the method of natural dispersal of pathogen propagules. Pathogens with air-dispersed spores are likely to have a larger genetic neighborhood than soilborne pathogens. But humans move many pathogens beyond their natural dispersal limits as a result of intercontinental travel and global commerce.
Reproduction and mating systems affect the way gene diversity is distributed within and among individuals in a population, leading to differences in genotype diversity. Pathogen reproduction can be sexual, asexual, or mixed (having both sexual and asexual components). Mating system is relevant only to the sexual component of reproduction, and can vary from strict inbreeding to obligate outcrossing. Some pathogens (e.g., all *Fusarium oxysporum* formae specialae and most bacteria) reproduce only asexually in agroecosystems. These pathogens exist as a series of discrete clones or clonal lineages with little evidence of recombination among clonal lineages. Populations of these pathogens usually exhibit a low level of genotype diversity. In strictly asexual pathogens, measures of genotype diversity are more meaningful than measures of gene diversity because most of the genetic diversity is distributed among clonal lineages. An advantage of sex is that, with each generation, new combinations of alleles come together through recombination, leading to an increase in genotype diversity that may enable some component of the pathogen population to survive in a variable and potentially hostile environment (e.g., on a resistant host). A disadvantageous result of sex is that fit combinations of alleles (coadapted gene complexes) are broken up through recombination, so it becomes difficult to maintain groups of alleles that offer an advantage in specific environments. Sexual pathogens usually exhibit a high degree of genotype diversity, so measures of gene diversity are needed to compare populations. Pathogens with mixed reproduction systems have significant advantages over strictly asexual or strictly sexual pathogens. During the sexual cycle, new combinations of alleles (genotypes) are produced that can be tested in different environments. During asexual reproduction, combinations of alleles (genotypes) that are most fit are held together through clonal reproduction and may increase to a high frequency. Thus these pathogens can exhibit high levels of both gene and genotype diversity. The spatial and temporal distribution of clonal lineages within and among populations will depend mainly on the dispersal of the asexual propagules. If asexual spores are capable of long-distance dispersal, then the clone with highest fitness can become distributed over a wide area through genotype flow relatively quickly.

Selection is the force that is most easily managed in agroecosystems. The strong directional selection that occurs when a major plant disease resistance gene becomes widely distributed drives the increase in frequency of the virulent pathogen mutant that has the corresponding virulence allele. The many examples of resistance genes that are overcome by new pathogen strains offer abundant evidence that selection is efficient in agricultural ecosystems that are based on monoculture and genetic uniformity. Resistance gene deployment strategies that impose disruptive selection, such as cultivar mixtures, can slow the evolution of pathogen populations and extend the usefulness of resistance genes.[3]

### AN EXAMPLE OF GENETIC STRUCTURE

By using selectively neutral genetic markers and hierarchical sampling to determine the genetic structure of pathogen populations, we can begin to understand the evolutionary forces that shaped these populations, and infer the importance of the individual evolutionary factors for each pathogen.[3] Commonly used DNA-based marker systems include RFLPs, microsatellites, AFLPs, and DNA sequences. DNA fingerprints are used to identify clones within pathogen populations. To determine whether a pathogen population has a sexual component of reproduction, it is common to clone-correct the dataset, using only one representative of each clone in the analysis of underlying allele frequencies. For diploid pathogens, the starting point is to test for departures from Hardy–Weinberg equilibrium. If a population is at Hardy–Weinberg equilibrium, then there is no deviation between expected and observed genotypic proportions within loci, and associations among loci are random, a state called gametic equilibrium. For haploid pathogens, it is common to test for departures from gametic equilibrium (a state called gametic disequilibrium) in a clone-corrected dataset to determine whether a pathogen population is undergoing sexual recombination. Comparisons between populations are made by comparing allele frequencies to obtain measures of genetic similarity. Population subdivision is measured using F-statistics (diploid pathogens) or Nei’s $G_{ST}$ (haploid pathogens).

From a population genetics perspective, the best characterized fungal pathogen at this time is *Mycosphaerella graminicola* (anamorph *Septoria tritici*), which causes the septoria leaf blotch disease on wheat.[4] Over 5000 isolates of *M. graminicola* from field populations around the world have been characterized for diversity in mitochondrial and nuclear genomes using a combination of RFLPs, DNA fingerprints, and DNA sequence loci. Field experiments were conducted to differentiate among the five evolutionary forces and obtain empirical estimates for each factor in an agricultural setting. Through population genetic analysis, we now know that *M. graminicola* has a mixed reproduction system, with sexual recombination occurring mainly between growing seasons but also during the growing season. Asexual spores move between plants by splash-dispersal and sexual ascospores move by wind. As a result, the typical field population is composed of a mosaic of overlapping clones, with few clones distributed over a spatial scale of more than a few meters. On average, each leaf is colonized by a different
pathogen genotype, and it is common to find many different genotypes within the same lesion on a leaf. Regular sexual reproduction maintains the two mating types at a 1:1 ratio through frequency-dependent selection, and unlinked loci are at gametic equilibrium. The genetic neighborhood is large as a result of long-distance movement of windblown ascospores, so that populations separated by 1000s of kilometers on the same continent are genetically very similar. Populations on different continents also are very similar, suggesting that the pathogen has been spread globally through infected seed. Approximately 80% of the world’s genetic diversity is found within an area 1 m$^2$ in any field sampled anywhere in the world. Populations are stable over time and a large number of alleles are found at individual RFLP loci, suggesting that effective population sizes are large (at least 70 individuals per square meter). Selection coefficients associated with specific clones competing in field experiments were large, illustrating the potential for rapid evolution in field populations. Taken together, these findings well explain the observed rate of evolution in populations of *M. graminicola*.

**CONCLUSION**

Knowledge of pathogen population genetics can be applied to the development of resistance breeding strategies and gene deployment that may lead to resistance that is durable over long periods in the field, and can guide disease management strategies.\(^{[1]}\) For example, a wilt pathogen such as *Fusarium oxysporum* that has low evolutionary potential as a result of strict asexual reproduction, low gene flow potential, and small population size may best be controlled by using single major resistance genes. A powdery mildew pathogen such as *Blumeria graminis* that has high evolutionary potential as a result of a mixed reproduction system, high genotype flow, and large population size may require quantitative resistance and an intensive resistance gene management strategy (such as cultivar mixtures) to obtain durable resistance.

INTRODUCTION

Bioengineered plants are being developed to produce a variety of recombinant macromolecules for biomedical and tissue and cell engineering applications. However, many of these therapeutics and biomaterials require posttranslational modifications for proper structural and functional characteristics, which are understudied in plants, especially in relation to the production of foreign proteins. Therefore an understanding and evaluation of some of the key biochemical events such as glycosylation and hydroxylation are essential before commercial-scale production and manufacturing of recombinant therapeutics can become commonplace. Here we provide a brief review of the various PTMs, with emphasis on glycosylation and hydroxylation, which affect proteins in the context of plant-derived recombinant therapeutics.

POST-TRANSLATIONAL MODIFICATIONS

Several eukaryotic proteins, including many proteins of therapeutic value, are processed by a series of modifications that occur during and after translation. These chemical modifications, called co- and post-translational modifications, play important roles in folding, structure, intracellular targeting, stability, and functioning of the proteins. Among PTMs, proteolytic cleavage, phosphorylation, glycosylation, and hydroxylation are some of the most frequently occurring and important modifications. All eukaryotic organisms can proteolytically cleave the initiating methionine and remove the N-terminal signal peptides on proteins destined for secretion. Phosphorylation and dephosphorylation of proteins are transient events and occur in all eukaryotic organisms.

Most cell surface and secreted proteins are non-reversibly glycosylated in the endoplasmic reticulum (ER) and the Golgi apparatus by covalent attachment of sugar residues to asparagine (N-glycans) or to serine/threonine (O-glycans) side chains in proteins, as described in the following sections. In some instances, glycans are subjected to further modifications such as acetylation, sulfation, or phosphorylation. Glycosylation is known to impart a wide variety of functions in the cells, and, in many instances, glycosylation affects protein structure, solubility, stability, and function.

N-Linked Glycosylation

N-linked glycosylation is a co- and post-translational modification event, and requires the consensus amino acid sequence, Asn–Xaa–Ser/Thr (Xaa=any amino acid except proline), for carbohydrate attachment in the ER. N-linked glycosylation is initiated by the transfer of a preformed 14-sugar oligosaccharide unit, GlcNAc2Man9Glc3 (GlcNAc=N-acetylglucosamine, Man=mannose, and Glc=glucose), from dolichol-pyrophosphate oligosaccharide to the appropriate asparagines (Asn) of the nascent polypeptide chain in the ER. All the further steps of glycan processing in the ER are catalyzed by specific exoglycosidases. Glucosidase I and II remove the glucose molecules, and α1–2 mannosidase removes mannose residues to generate the GlcNAc2Man8 structure. These structures are transported to the Golgi apparatus, where further trimming of mannose residues takes place followed by addition of monosaccharides, which is carried out by sugar and linkage-specific glycosyltransferases. Eukaryotic expression systems (e.g., yeast, insects, plants, and mammals) are able to perform both N-linked and O-linked glycosylation. The initial steps of N-linked oligosaccharide biosynthesis in the ER are similar in all eukaryotic organisms. However, there are significant differences in the glycosylation process in the Golgi complex, resulting in distinct final glycan motifs in all these organisms.

In mammalian cells, N-linked oligosaccharide chains often possess terminal sialic acid (SA) and penultimate galactose (Gal) residues at the nonreducing end. These reactions are carried out by linkage-specific and substrate-specific sialyltransferases and galactosyltransferases,
respectively. The presence of terminal SA residues is, in most cases, essential for the extended half-life of the glycoproteins in the animal serum. Glycoproteins lacking SAs on their glycan chains are recognized as “foreign” by asialoglycoprotein receptors and immune cells, quickly removed from the serum, and destroyed. This property renders many nonmammalian-derived glycoproteins unacceptable for human therapeutics. Fungi (Saccharomyces cerevisiae, Pichia pastoris, and Aspergillus niger) are unable to process the oligomannose chain to hybrid and complex glycans; instead, fungi perform hypermannosylation, resulting in up to 50 (or more) mannose residues per glycan chain. Insect cells have the ability to perform sialylation either by their intrinsic nature, as shown with recombinant tissue plasminogen activator (tPA), by manipulation of culture conditions, or by metabolic engineering.\textsuperscript{[7–9]}

To date, no reports have been published regarding whether or not plants are able to perform sialylation on glycoproteins. However, significant progress has been made in recent years toward humanizing the glycan chains on plant-derived glycoproteins. Palacpac et al.\textsuperscript{[10]} and Bakker et al.\textsuperscript{[11]} described the expression of mammalian β1–4 galactosyltransferase in cultured tobacco BY2 cells and tobacco plants, respectively. Both groups of researchers were able to produce N-linked oligosaccharide structures terminating with Galβ1–4 linked to GlcNAc. The Arabidopsis genome database contains evidence of putative genes homologous to mammalian sialyltransferases and CMP-SA transporter genes, indicating that the genomic machinery to perform sialylation may exist in plants (MIPS Arabidopsis thaliana database).

Plant-derived glycoproteins also carry an α1–3-linked fucose (Fuc) on the proximal GlcNAc residue as well as a β1–2-linked xylose (Xyl) on the core mannose residue. According to some researchers, these two “plant-specific” sugar residues are immunogenic in mammalian systems.\textsuperscript{[12]} However, there are reports suggesting that the presence of these residues does not alter the immunogenicity of the plant-derived glycoproteins.\textsuperscript{[13]} The issue of immunogenicity/antigenicity of plant-specific glycans needs further attention.

**O-Linked Glycosylation**

 Addition of glycans to the hydroxyl group of serine or threonine amino acid residues is known as O-linked glycosylation. In some cases, glycans are added to hydroxylysine, such as in collagen, or hydroxyproline, such as in plant cell wall glycoproteins. Unlike N-linked glycosylation, O-glycosylation occurs (initiation and maturation) in the Golgi complex and does not require a lipid-linked carrier such as dolichol-phosphate. Each monosaccharide is added in a sequential manner to generate a short (one to four sugar residues per glycosylation site), linear, or biantennary oligosaccharide structure bound to the protein. Moreover, the requirements of a consensus amino acid sequence is not clear. As O-glycosylation occurs on a fully folded protein, only serine or threonine on the surface of a protein can be O-glycosylated. Addition of N-acetylgalactosamine (GalNAc) to serine/threonine is the most common type of O-glycosylation in mammals, which is commonly known as mucin-type, core-1 (Galβ1–3GalNAcz-O-Ser/Thr) glycosylation. Core-1 is generated by the action of UDP-GalNAc:polypeptide N-acetylgalactosaminyltransferase (GalNAc transferase) and core-1 β1–3 galactosyltransferase. Core-1 structure can be extended by the action of linkage-specific sialyltransferases and GlcNAc transferases.\textsuperscript{[15]}

N-glycosylation on recombinant proteins, and its biosynthetic pathway, is relatively well studied in plants, but very little is known about mammalian-like O-linked glycosylation on plant-derived recombinant proteins. A quick search of the Arabidopsis genome reveals the presence of candidate glycosyltransferases involved in O-glycosylation that are waiting to be characterized and functionally assigned (MIPS Arabidopsis thaliana database). Recently, the Galβ1–3GalNAc disaccharide conjugated to a rice seed protein, glutelin, was reported. This study demonstrated that plants have the ability to recognize Ser/Thr as potential O-glycosylation sites and perform core-1 O-glycosylation.

**Hydroxylation**

Hydroxylation is the addition of an –OH group to the side chain of specific amino acids and occurs in many eukaryotic proteins. Lysine and proline are the two most common amino acids targeted for this modification. In plants, 4-hydroxyproline is primarily found on cell wall proteins known as hydroxyproline-rich glycoproteins (HRGPs) such as extensins, 4-hydroxyproline-rich lectins, and arabinogalactan proteins. Extensins, a family of insoluble plant cell wall glycoproteins, are the best-characterized HRGPs that contain multiple repeats of the pentapeptide Ser–4Hyp–4Hyp–4Hyp–4Hyp– sequences interspersed with tripeptide TyrLysTyr units. Most of the 4-hydroxyproline residues are O-glycosylated with oligoarabinosides. There is no published report on lysine hydroxylation on plant proteins.

In animals, 4-hydroxyproline, 3-hydroxyproline, and hydroxylysine are found primarily on collagens and other collagen-like proteins such as C1q of complement,
acetylcholinesterase, and mannose-binding proteins. The stability of collagens and collagen-like triple-helical domains in other molecules at physiological temperature is determined, to a large extent, by the hydroxylation of proline residues.

Prolyl 4-hydroxylase (P4H) (EC 1.14.11.2; procollagen-proline, 2-oxoglutarate 4-dioxigenase) catalyzes the formation of 4-hydroxyproline in collagens and other proteins with collagen-like sequences by hydroxylyating preferably proline residues in the Y-positions of the –X–Y–Gly– sequences. In vertebrates, the enzyme is an $\alpha_2\beta_2$ tetramer with a molecular mass of about 240,000 Da, consisting of two types of monomers with molecular masses of about 63,000 Da ($\alpha$ subunit) and 58,000 Da ($\beta$ subunit). Subcellular fractionation studies have demonstrated that P4H is located in the rough ER, and both the active enzyme tetramer and the protein disulfide isomerase (PDI) subunit ($\beta$) are soluble ER luminal proteins. The polypeptide chains of the fibril-forming collagens vary in their hydroxyproline content, in the range 92–126 residues per 1000 amino acids. Approximately 50% of the proline residues are hydroxylated.[18]

The genome of Arabidopsis thaliana encodes six P4H-like polypeptides, one of which, a 283-residue soluble monomer, was cloned and characterized. Catalytically critical residues identified in animal P4Hs are conserved in this P4H, and mutagenesis of these residues led to complete or almost complete inactivation. The recombinant Arabidopsis P4H, effectively hydroxylated poly(1-proline) and many synthetic peptides corresponding to proline-rich repeats present in plant glycoproteins and other proteins. Surprisingly, collagen-like peptides were also good substrates, with the $V_{\text{max}}$ with (Pro–Pro–Pro)5 similar to that with poly(1-proline). The other five Arabidopsis P4H polypeptides have yet to be characterized.[19]

In previous reports, plant cells were cotransformed with chimeric nonplant P4H to achieve hydroxylation of proline residues.[20] However, with the cloning, characterization, and structural improvements of Arabidopsis P4H, the use of plant P4Hs to efficiently hydroxylate prolines may be a possibility in the near future.

CONCLUSION

Most eukaryotic proteins undergo cotranslational modification and PTM. There are over 200 PTMs known to date that occur on the N-terminus or C-terminus of the polypeptides and side chains of amino acids. Many proteins of pharmaceutical importance require some of these PTMs for their physicochemical and physiological states. Plants are able to perform most of the mammalian-like PTMs, but the structural and underlying molecular and biochemical details of these modifications are very limited. With the emerging importance of plants as suitable expression systems for biomedically important proteins, a better understanding of plant PTMs is required.

Potassium and Other Macronutrients

Patrick H. Brown
University of California, Davis, California, U.S.A.

INTRODUCTION

The mineral nutrients K, Mg, Ca, and S are unique and highly varied with respect to their acquisition from the soil, distribution within the plant, metabolic roles, and deficiency responses. An exhaustive analysis of these processes is beyond the scope of this article, thus only a brief overview is provided. For each element, however, a more detailed description of a single physiological process that is either unique or broadly illustrative of an important principle in plant nutrition is provided.

POTASSIUM

Potassium is the most abundant univalent cation in the cytoplasm of plants. It forms only weak complexes and does not compete strongly with other cations in metabolic reactions. As a consequence of these physical and chemical characteristics, K is uniquely suited to serve as the primary inorganic cellular osmoticum and, through the reversible formation of complexes with soluble and insoluble anions, as a cytoplasmic pH buffer. The critical functions of K in plants include osmoregulation, turgor-related processes (e.g., tropisms, stomatal opening, and cell expansion) and counterbalancing of ions in the movement of sugars into the phloem.

Uptake and Cellular Compartmentation

The importance of K as a cellular osmoticum and pH buffer requires that the uptake and cellular compartmentation of K be tightly regulated and highly responsive to changes in local K availability and cellular K demand. The mechanism of transport of K across membranes is the best studied of all mineral elements and is broadly illustrative of the process of nutrient acquisition and regulation in plants.

In the early 1950s Emmanuel Epstein and colleagues at the University of California, Davis, provided important early insights into nutrient uptake by plants. Two mechanisms were postulated. The first, or high-affinity, system operated at low external concentrations of K, was saturable, and could be described by Michaelis-Menton kinetics. A second mechanism operating at higher concentrations of K was postulated to be present either in the same or in different membranes (i.e., plasma membrane and tonoplast, respectively). With the completion of the genomic sequence from Arabidopsis and the advent of powerful molecular and biophysical techniques, it is now clear that transport of K is even more complex than originally envisioned. At least three gene families with a total of 34 individual genes are known to contribute to K uptake and transport. The various K transporters differ in their affinity for K and the specific mechanisms by which they facilitate uptake of K. These can be divided into high-affinity carriers (such as HKT1) and low-affinity channels, of which there are many examples (e.g., the KAT and SAT families). The HKT1 gene functions as a Na-K cotransporter that at high concentrations of Na preferentially transports Na and as such may contribute to salinity stress. The exact mode of action of these transporters remains uncertain, although the large number of K transporters with apparent redundancy likely provides plants with the capacity for closely regulated uptake of K under a variety of environmental conditions.

Functions of Potassium

The majority of functions associated with K occur by virtue of its role as an osmoticum for turgor-driven processes, as a counterion for charge balance associated with H⁺ and solute transport, and as a stabilizer of enzymes and proteins. The processes of both cell expansion and stomatal opening involve the active transport of large amounts of K into the vacuole. The subsequent accumulation of water in the cell results in the increase in cell turgor required for stomatal opening and cell expansion. Potassium functions in photosynthesis as the dominant counterion to photosynthetic H⁺ flux across the thylakoid membranes of chloroplasts. Potassium facilitates the loading of sucrose into phloem by providing the required osmotic potential in source tissues and through its role as a counterion for sucrose and H⁺ transport into phloem sieve tubes.
Deficiencies of Potassium

Potassium is sometimes required in amounts that equal or even exceed the requirement for nitrogen in crop plants that produce large amounts of carbon-rich structures such as grains, fleshy fruits, tubers, and nuts. The characteristic symptoms of K deficiency include marginal and tip burn of mature leaves. This is a consequence of the high mobility of K in the plant that favors K movement from old to young plant parts and of the role of K in water relations of the leaf.

CALCIUM

Plants require substantial amounts of Ca. Among the mineral nutrients, only N and K are required at higher concentrations. The functions of calcium in the plant fall broadly into two categories—structural and signaling. The structural role involves the formation of stable but reversible complexes in the cell wall and membrane. The signaling role is critical in several signal transduction pathways.

Uptake and Cellular Compartmentation

The majority of Ca in the cell is found in the apoplasm where it is either strongly bound in structures or present in exchangeable pools in cell walls or at the external surface of the plasma membrane. Calcium is not freely mobile in the phloem and is delivered to growing cells largely through xylem flow. As a consequence, Ca concentrations increase with tissue age and the supply of Ca may be inadequate to satisfy demand in apical meristems, leaf

![Diagram](https://www.dekker.com)

**Fig. 1** A three dimensional molecular model of the Type I (non-grass) and Type II (grass) wall shows the molecular interactions between cellulose, xylol glucans, pectins and wall proteins. Pectin in the cell wall provides sites for Ca binding which then cross link with adjacent pectin HGA to form junction zones. The density of these junction zones and the degree of esterification as well as the distribution of borate di-esters (not shown) influences cell wall pore size, structure and function. (View this art in color at www.dekker.com.)
tips, and fruits with poor vascular connectivity and rapid growth. In contrast to the highly variable and unregulated accumulation of Ca in the apoplast, cytoplasmic Ca concentrations are extremely low and highly regulated. No fewer than four families of Ca channels, as well as a Ca\(^{2+}\)-ATPase, have been found in the plasma membrane, rough ER, tonoplast, and mitochondrial membranes. Two of these channels can be activated by ligands, whereas others are sensitive to voltage changes or activated by mechanical stretching.

**Functions of Calcium**

In plant cell walls the cellulose-xyloglucan framework is embedded in a pectin matrix. Pectin methylesterase in the cell wall cleaves some of the methyl groups from homogalacturonan (HGA) and provides sites for Ca binding, which then cross-link with adjacent HGA to form junction zones. The density of these junction zones and the degree of esterification as well as the distribution of borate diesters influences cell wall pore size\(^3\) (Fig. 1). In fruit ripening there is a solubilization of Ca that precedes the softening process. Spray application of Ca to fruits is widely practiced to increase the concentration of Ca in tissue and to delay fruit softening.

Calcium plays a critical role in the stabilization of the plasma membrane and is essential for the activity of membrane-bound enzymes and selectivity of ion uptake. In the absence of adequate Ca, membranes become leaky and ultimately disintegrate with a loss of cell

![Fig. 2](View this art in color at www.dekker.com.)

Interactions of intracellular and extracellular Ca\(^{2+}\) in cell signaling. The relationships of Ca\(^{2+}\) stores in plant cells are known to be complex, concentrations of Ca\(^{2+}\) being high in organelles and in the cell wall and low in the cytoplasm. When the cell is signaled, channels are opened in various organelles or in the plasma membrane, allowing Ca\(^{2+}\) to enter the cytoplasm by diffusing down its electrochemical gradient. Ca\(^{2+}\) ATPases and perhaps Ca\(^{2+}/H^+\) antiporters return the cytoplasmic concentration to resting value. Where known, subcellular concentrations of Ca\(^{2+}\) are indicated (quoted values in the ER vary from 0.1 to 1 mM). The concentration of cytoplasmic binding sites has been measured at about 0.15 to 1 mM. Free cytoplasmic Ca\(^{2+}\) is in equilibrium with these binding sites. Increases of cytosolic calcium, [Ca\(^{2+}\)], activate calmodulin, thereby initiating subsequent downstream events. \(\text{IP}_3\), inositol 1,4,5-triphosphate. compartmentation. A primary consequence of saline stress occurs when Na replaces Ca at membrane-binding sites, resulting in a loss of membrane functionality.

The internal concentration of Ca, [Ca$^{2+}$], is a principle component in signal transduction pathways in plant cells. This role of Ca requires that cytosolic Ca concentrations (100–200 nM) be maintained many orders of magnitude lower than in the cell wall (1–10 mM). Changes in cytosolic Ca occur in response to a variety of environmental and developmental cues that initiate an opening of Ca channels and a rapid transient increase in [Ca$^{2+}$]. The increase in cytosolic [Ca$^{2+}$] activates numerous Ca$^{2+}$-binding proteins (calmodulin and calmodulin-like protein kinases) that bind and activate a variety of target proteins. In this manner, changes in [Ca$^{2+}$] initiate a wide range of responses, including stomatal closure, gravitropism, pollen tube orientation, and many others. The increase in [Ca$^{2+}$] is dissipated by Ca-ATPases located in the tonoplast, ER, and plasma membrane (Fig. 2).

**Deficiencies of Calcium**

The critical role of Ca in cell wall formation and membrane stability requires that Ca always be present in adequate amounts in all meristematic tissues. Calcium transport within the plant, however, is largely passive, being driven by water movement and local diffusion. Only very limited Ca movement occurs in the phloem. Calcium deficiency often results in a rapid inhibition of growth and subsequent tissue necrosis. In fleshy organs (fruits, tubers), Ca deficiency results in membrane leakiness, reduced cellular cohesion, and enhanced tissue breakdown. This is particularly evident in fast-growing tissues where demand might exceed supply. Leaf tip burn in lettuce, bitter pit in apple, and blossom end rot in tomato are examples of disorders that are induced by Ca deficiency. Correction of these disorders requires that Ca supply be maintained throughout plant growth. Supplemental Ca applications postharvest can significantly increase storage life of fruits and vegetables.

**Magnesium**

Magnesium is a divalent cation that functions primarily through the formation of ionic complexes with nucleophilic ligands and as a bridging molecule between phosphoryl groups and other molecules or enzymes. Magnesium uptake likely occurs through both channels and ATP-dependent pumps; however, the specific mechanisms of Mg transport are poorly understood. K$^+$, NH$_4^+$, Ca$^{2+}$, and Mn$^{2+}$ each compete with Mg$^{2+}$ for uptake and cause Mg$^{2+}$ deficiency in plants from many environments.

**Functions of Magnesium**

Magnesium is essential for chlorophyll. Consequently, chlorosis and reduced photosynthesis are primary consequences of Mg deficiency. Depending upon Mg supply, Mg in chlorophyll varies from 6–60% of total cellular Mg. Magnesium also influences photosynthesis through its role as a regulator of Calvin cycle enzymes such as RuBisco and fructose 1,6 bisphosphatase. Magnesium functions as a bridging moiety between enzymes and ATP. Hence, the substrate for ATP-ases, as well as inorganic polyphosphatases, is Mg-ATP rather than free ATP. In roots with sufficient Mg, as much as 90% of cytoplasmic ATP is complexed to Mg. Furthermore, ATP synthesis has an absolute requirement for Mg.

**Deficiency of Magnesium**

Intervenial chlorosis of the oldest leaves is a characteristic symptom of Mg deficiency. This is a consequence of the role of Mg in chlorophyll synthesis and the high mobility of Mg that results in export of Mg from old tissues to young when Mg becomes limiting. In many Mg-deficient crops, photosynthate accumulates in source leaves as transport to sinks is inhibited.

**Sulfur**

Sulfur is primarily acquired by plants as the sulfate anion (SO$_4^{2-}$). The majority of the SO$_4^{2-}$ that enters the plant is then reduced to cysteine and is subsequently converted to methionine and a variety of secondary sulfur-containing molecules. Unlike nitrogen, which is always utilized in the reduced form, SO$_4^{2-}$ may be directly incorporated into a variety of sulfated compounds, including sulfolipids in plant membranes. Animals and humans cannot reduce sulfur, and hence require dietary sources of cysteine and methionine to provide their sulfur needs.

**Sulfate Uptake and Transport**

Sulfate is relatively abundant in the environment, particularly in industrialized regions where gaseous SO$_4^{2-}$ is present as a pollutant. Sulfate uptake is primarily mediated by a family of proton cotransporters located in various plant membranes. 13 SO$_4^{2-}$ transporter genes have been identified in Arabidopsis. Many of these genes respond differently to SO$_4^{2-}$ availability, and the full complex of transporters is likely essential for the normal regulation of sulfur metabolism.
Functions of Sulfur

Sulfur-containing compounds function in a diverse array of metabolic processes, including as structural components of proteins and membranes; in redox and methyl-group transfer and oxidation reactions; and in the detoxification of herbicides, heavy metals, and oxidants. Sulfur-containing coenzymes and vitamins—including the ethylene and polyamine precursor S-adenosyl-L-methionine, coenzyme A, and S-methylmethionine—participate in group transfer and

Fig. 3 Overview of sulfur metabolism, reduction, and transport in plants. Like nitrate, sulfate uptake across the plasma membrane is energized by an electrochemical gradient that is maintained by a proton-pumping ATPase. Sulfate is stored in vacuoles. Reduction of sulfate and its assimilation into cysteine take place in plastids of root and leaf cells. APS, 5-adenylsulfate; PAPS, 3phosphoadenosine-5'-phosphosulfate. (View this art in color at www.dekker.com.)
methylation reactions in a variety of metabolic pathways (Fig. 3). The thiol group of cysteines present in proteins can be oxidized, allowing for the formation of disulfide bonds between adjacent cysteine residues. These cross-links are central in determining the tertiary and quaternary structure of proteins. The dithiol–disulfide interchange also occurs in a variety of sulfur-containing molecules (thioredoxin, glutaredoxin, and glutathione) and is critical for the maintenance of cellular redox potential. Glutathione, the major nonprotein thiol in plants, is central for cytoplasmic redox regulation, sulfur storage, heavy metal detoxification, environmental stress tolerance, and as a precursor to phytochelatins. Glutathione detoxifies many toxins and herbicides through the formation of glutathione conjugates that are transported to the vacuole by an ATP-binding cassette (ABC) transporter. Glutathione is also the precursor to phytochelatin ((γ-Glu-Cys)ₙ Gly), which plays a critical role in the detoxification of heavy metals such as Cd.

**Sulfur Deficiency**

Sulfur requirements (0.1 to 0.5%) vary between families (Gramineae < Leguminosae < Cruciferae) and reflect differences in sulfur content of proteins in these families. The most prominent feature of S deficiency is chlorosis, which occurs uniformly throughout the plant. The sulfur content and concentration of proteins declines in grains during storage and results in important changes in quality (in the case of baking flour) and value as animal feed. Deficiencies of S are most common in acid and leached soils but are becoming more prominent worldwide as levels of pollutant S in the air decline.

INTRODUCTION

During most of the 150,000 year history of humanity, people survived by the hunting and gathering lifestyle. Throughout this extensive period, many cultural groups developed a sophisticated understanding of the inner workings of nature. Hunter-gatherer groups around the world have relied upon hundreds of wild plant species for basketry, ceremonies, foods, furniture, poisons, traps, and weapons for millennia. Their hard-earned, detailed traditional ecological knowledge included information about how wild plants respond to gathering and cultivation. For certain plant species, indigenous people practiced judicious harvesting, adjusting the variables (season, frequency, pattern, scale, intensity, tool) of collecting to influence the growth and abundance of native plant populations. Prior to the invention of agriculture, many areas were also actively managed for increased densities and abundance of wild plants to meet an array of cultural needs. The land management practices that predate agriculture included burning, irrigating, pruning, transplanting, weeding, sowing, and tilling, applied to a multitude of habitat types. This article discusses examples of these practices, along with their potential ecological consequences, and puts forth a view of human-plant interactions as part of a continuum from gathering to domestication.

WILD PLANT MANAGEMENT FOR FOODS

Wild plant gathering for food was traditionally a female responsibility in most hunter-gatherer groups, whereas hunting and fishing were male activities. Many different kinds of plant parts were harvested for food. Small seeds and grains of wildflowers and grasses, and underground swollen stems from herbaceous plants are discussed here (Fig. 1, Tables 1 and 2).[1,3]

Wildflower Seed and Grass Grain Management

Today, cereal grains such as wheat, oats, barley, rice, and corn are the most important of all food crops in the world. One of the oldest forms of sowing in the world is the broadcasting of fruits of wild grasses and the seeds of wildflowers for food. This involves grain and seed selection, saving, and dispersing, often after some kind of ground preparation. It is from this repeated act of broadcasting, together with certain modes of harvesting, that cereal domestication arose.[4] The harvesting strategy of seedbeating coupled with the horticultural techniques of saving and sowing seed, in conjunction with fire management, created ecological effects at the species, population, community, and landscape levels (see Fig. 2A). Seedbeating plants, burning vegetation, and sowing seed tended to select for specific genotypes that hold up well to and even thrive under human harvesting and management regimes.

The Bagundji traditionally repeatedly fired the grasslands in what is now New South Wales, Australia, to increase seed production of Mitchell grass (Astrebla pectinata). Patches of grass and brush were burned over to ensure a better crop of edible seeds by the Northern Tonto, Southern Tonto, and White Mountain Apache of the American Southwest. The Southern Paiute of the Great Basin sowed the seeds of Indian rice grass (Achnatherum hymenoides). California provides many case examples of tribes managing numerous landscapes to foster the growth and abundance of herbaceous plants for edible seed. The Central Sierra Miwok of the Sierra Nevada cultivated six kinds of seeds with burning, sowing, and harrowing in the Sierra Nevada foothills. Two of these are farewell-to-spring (Clarkia purpurea ssp. viminea) and mule ears (Wyethia helenoides). The Modoc, east Shasta, Achomawi, Northern Maidu, and Nisenan tribes of northern California sowed the seeds of many kinds of wild herbaceous plants.

Bulb, Corm, and Tuber Management

Perennial plants with underground storage organs offer rich sources of starch and other carbohydrates, as well as substantial protein and trace minerals. They were dug with a digging stick by hunter-gatherer groups (see Fig. 2B). Prior to domestication of the onion, potato, cassava, yam, and other underground swollen stems, indigenous people all over the world cultivated subterranean organs of wild plants for foods. This activity was perhaps the oldest form of tillage—one that became the precursory management
regime and provided the ecological foundation for the development of root crop agriculture in many areas. Specific strategies were employed to perpetuate populations of favored plants, such as 1) replanting of cormlets and bulblets; 2) deliberately breaking of the bulb above the root crown, leaving some stem and root tissue; 3) leaving an upper section of the tuber with a vine stem; 4) weeding around favored plants; 5) and burning of areas to decrease plant competition and recycle nutrients. Through human selection, protection, and replanting of offsets, certain geophyte species have probably undergone genetic changes. The excavation of plants with vegetative reproductive parts and the replanting or breaking off of such parts would likely select for specific genotypes that benefit under human disturbance regimes.[5] Gidjingali women in Arnhemland, Australia, still gather wild ganguri, a type of yam (Dioscorea transversa), with a digging stick, being careful to leave the vine stem and a small section of tuber behind, replanting it so that it will grow again. The San of South Africa traditionally burned the veldt at the end of the dry season to promote the growth and abundance of edible bulbs and tubers. The Nez Perce of the eastern Columbia Plateau in North America harvested camas (Camassia quamash), returning immature bulbs and half of the mature ones to the soil. The preferred digging season was after the seeds set to ensure a future supply. The Western Mono and Sierra Miwok of California harvested the corms of blue dicks (Dichelostemma capitatum), purposely breaking off the cormlets and replanting them.

WILD PLANT MANAGEMENT FOR BASKETRY

Making baskets is a worldwide phenomenon. Roots and branches of trees and shrubs, and the leaves and rhizomes of grasses, sedges, and ferns must be pliable, straight, long, and uniform, without insect or disease damage. Yet wild plants often exhibit crooked, brittle growth, with evidence of insects or diseases, making them unsuitable for basketry. However, with proper management, these plants can be transformed into beautiful and functional baskets.

Fig. 1 Native plants used by the pre-agricultural people of California. (A) Soaproot (Chlorogalum pomeridianum)—a very important plant to the majority of California tribes. The bulbs provided glue, fish poison, and food; the old leaf sheaths that clothe the bulb formed the bristles for brushes. The young edible leaves were roasted. The plant is still gathered today. (B) Flowerstalks of deergass (Muhlenbergia rigens)—a perennial bunchgrass—are utilized in the foundation of coiled baskets by numerous California Indian tribes. (C) The now rare and endangered Hall’s Wyethia (Wyethia elata) that grew prolifically in the montane forests kept open by Indian-set fires were significant for their edible seeds, gathered by the Western Mono of the western Sierra Nevada mountains.

</thead>
<tbody>
<tr>
<td>Burning</td>
<td>Application of fire to particular vegetation areas under specified conditions such as seasonality, fire return interval, and aerial extent to achieve select cultural purposes.</td>
<td>The Australian aborigines of Victoria dug up tubers of murnong (<em>Microseris scapigera</em>); gathering areas were historically burned over to increase production.</td>
</tr>
<tr>
<td>Irrigating</td>
<td>To supply select land areas with water by means of artificial channels.</td>
<td>The Owens Valley Paiute of the Great Basin artificially watered a host of plants such as wheat grass (<em>Agropyron</em> sp.), Great Basin wild rye (<em>Elymus</em> sp.), and blue dicks (<em>Dichelostemma capitatum</em>) to increase their productivity and abundance.</td>
</tr>
<tr>
<td>Pruning</td>
<td>To remove dead and living parts from native plants to enhance growth, form, fruit, or seed production.</td>
<td>The Timbisha Shoshone of the Great Basin pruned honey mesquite (<em>Prosopis glandulosa</em>), a very important food resource, keeping areas about the trees clear of undergrad, dead limbs, and lower branches.</td>
</tr>
<tr>
<td>Sowing</td>
<td>The broadcasting of seed collected from native plants to an area (usually recently burned ground).</td>
<td>The Lummi Straits, Nooksack, and Nuuwhaha of the Pacific Northwest harvested the bulbs of camas (<em>Camassia</em> spp.) and placed broken stalks bearing ripe seed capsules into holes before they were recovered.</td>
</tr>
<tr>
<td>Tilling</td>
<td>The moving of soil to harvest underground perennial plant organs (e.g., roots, rhizomes, corms, bulbs), frequently followed by dividing of organs, leaving individual fragments or smaller clumps in soil.</td>
<td>The Dena’ina of Alaska purposely left fragments of underground swollen stems behind when digging to ensure the growth of new plants.</td>
</tr>
<tr>
<td>Weeding</td>
<td>Removing unwanted plants near favored plants.</td>
<td>Stands of sedge (<em>Carex barbareae</em>) along lowland creeks and rivers in central and coastal California were intensively weeded to encourage production of long, creeping rhizomes for use as weft or lacing in basketry by the Pomo, Ohlone, and other tribes.</td>
</tr>
</tbody>
</table>
for harvest. Many hunter-gatherer groups traditionally managed plant populations with burning, pruning, coppicing (severe pruning), and/or weeding to create useful growth. Clumps of beargrass (*Xerophyllum tenax*), a plant of widespread use for overlay designs in baskets of the Pacific Northwest, were burned periodically by the Hupa, Karuk, Yurok, Chilula, and other tribes of northern California and Oregon to increase the production of stronger, more supple leaves. Over half the tribes in California relied on the harvesting of the flowering culms of deergrass (*Muhlenbergia rigens*) for the foundation (or stuffing) of their coiled baskets, and these culms are still gathered today. An ancient tradition among many tribes was to burn colonies of this perennial bunchgrass every two to five years to enhance flowering stalk production, clear out detritus, and keep shrubs and trees from encroaching. The Cibecue and White Mountain Apache in eastern Arizona burned willow (*Salix* sp.) and sumac (*Rhus trilobata*) to bring out the young shoots for basket weaving. Burning, pruning, or coppicing shrubs and trees such as maple (*Acer macrophyllum*), redbud (*Cercis occidentalis*), deerbrush (*Ceanothus integerrimus*), hazelnut (*Corylus cornuta* var. *californica*), and willow (*Salix exigua*) were standard practice among tribes throughout California. Willows and other species of shrub are subject to attack by a wide range of leaf-eating, stem-sucking, and wood-boring insects. Fire is also an effective agent to combat many kinds of diseases and insects.\[6\]

**VIEWING HUMAN-PLANT INTERACTIONS AS A CONTINUUM**

In the repetitive gathering and cultivating of wild plant populations in specific areas over many years, nature was transformed at different scales of biological organization, from genetic to landscape scale. Thus, domestication of plant species grew out of a set of comprehensive land management systems and complex traditional ecological

---

Fig. 2  Plant gathering and management techniques used by the pre-agricultural people of California. (A) Cecilia Joaquin, a Central Pomo woman, collecting seeds with a seedbeater prior to 1924. Beating seeds of wildflowers and grasses with a shallow basket into a collection basket for food was the first in a series of management steps. Afterward, areas were burned to reduce plant competition and recycle nutrients; some of the seed was saved and broadcast in the burned area. These practices are recorded for tribes throughout western North America. (Photograph by Edward Curtis, courtesy of the National Anthropological Archives, Smithsonian Institution, #75-14715.) (B) A Wintu couple, Rosa Charles and Billy George, digging for yampah (*Perideridia* spp.) in 1931. The digging of many different kinds of bulbs and tubers with a hardwood digging stick, replanting propagules, and burning over areas to increase numbers, densities, and size of subterranean organs of wild plants for food was a common practice throughout the world. These had subtle yet significant effects in shaping the ecology of many ecosystems. (Photograph by J.P. Harrington, courtesy of the Santa Barbara Museum of Natural History.)
knowledge already in place in many different parts of the world for thousands of years prior to the origin of agriculture. Therefore, the distinction between domestic and wild in plant exploitation is not a sudden or marked change, but a gradual transition. Human-plant interactions can be appropriately viewed as a continuum from gathering to tending, to cultivation, to domestication.\textsuperscript{[7,8]}

In areas where plant domestication or the practice of agriculture never occurred, long-term cultivation practices with wild plants would still very likely lead to genetic changes that make plants better suited to the conditions of human-disturbed environments—such as burned over areas—and less adapted to the conditions of natural environments. The pathway of vegetation change that leads to seed domestication, for example, is probably a similar one in different areas. This pathway starts with selection pressures on plants in areas that are harvested repeatedly. Nevertheless, certain types of harvest methods will not automatically lead to selection of the corresponding domestication trait (i.e., lack of seed dispersal). For example, beating wild plants to harvest seeds (Fig. 2A) will select against any mutant that has a stiff rachis. Thus, the selection pressure exerted in this case will not lead to domestication, at least from the standpoint of seed dispersal. Further along the pathway to vegetation change is the actual burning of areas, preparation of soil, sowing of seed, and harrowing of brush. These activities can, over time, favor specific features of the seed or plant, and produce faster or more robust growth, which favors survival and flourishing with reliable production to the point where full domestication is not necessary. The evolutionary modifications are significant enough to lead to incipient or intermediate states of domestication. It is proposed that these intermediate states are evident in certain kinds of

\begin{figure}
\centering
\includegraphics[width=\textwidth]{fig3.png}
\caption{The continuum of human-induced vegetation change from gathering to domestication can be conceptualized as two major stages on a gradient of ecological change induced by human modification. These stages are not clear-cut, but grade into each other. The diagram does not imply that given enough time, hunter-gatherers would advance from one level of interaction with plants to the next.}
\end{figure}
native plants labeled as wild. It can be postulated that systems of seed production of hunter-gatherer groups in many parts of the world evolved to a point on the continuum of human-plant interaction that stopped short of the endpoint of full domestication (see Fig. 3). Thus, domestication is but one kind of biologically defined symbiotic relationship, and the manipulation of wild plants for edible seeds is an example of the many other types.\[9\]

Protein Quality in Transgenic Plants: Improvements

Jesse M. Jaynes
Kennesaw State University, Kennesaw, Georgia, U.S.A.

INTRODUCTION

Past expansions of the world’s food supply have relied primarily on plant breeding directed toward improving yields, increases in available cultivable lands, and augmentation of irrigation techniques. Because we are now encountering further constraints in all of these areas, future emphasis must include enhancing the “nutritional content” of the world’s basic food and feed crops, especially those that are indigenous to developing nations. Such nutritional enhancement can result in lowering per capita intake of plant-based food crops, ultimately making more food available for expanding populations. These developments are made possible through advances in the fields of biochemistry and molecular biology, which has caused the “biotechnology revolution.”

The composition of plant storage proteins, a major food reservoir for developing seeds, roots, and tubers, determines the nutritional value of plants and grains when they are used as foods and feed for humans and domestic animals. The amount of protein varies with genotype or cultivar, but in general, cereals contain 10% of the dry weight of the seed as protein, while in legumes, the protein content varies between 20% and 30% of the dry weight. Roots and tubers retain far less, generally around 2–3%. In many seeds, storage proteins account for 50% or more of the total protein and thus determine the protein quality of seeds. Each year, the total world cereal harvest amounts to some 1700 million tons of grain. This yields about 85 million tons of cereal storage proteins harvested each year and contributes about 55% of the total protein intake of humans. It has been difficult to produce significant increases in the level of protein and essential amino acids of crop plants utilizing classical plant breeding approaches. This is primarily because of the fact that the genetics of plant breeding is complex and that an increase in either trait may be offset by a loss in other agronomically important characters. In addition, it is probable that the storage proteins are very conserved in their structure and their essential amino acid composition would be little modified by these conventional techniques.

With respect to human and animal nutrition, most seeds do not provide a balanced source of protein because of deficiencies in one or more of the essential amino acids in the storage proteins. Consumption of proteins of unbalanced composition of amino acids can lead to a malnourished state which is most often found in people inhabiting developing countries where plants are the major source of protein intake. Thus the development of a more nutritionally balanced protein for introduction into plants takes on extreme importance.

PAST WORK

Over the last two decades, much work has been performed in an attempt to improve the nutritional quality of plant storage proteins by transferring heterologous storage protein genes from other plants. The development of genetic engineering and the various gene transfer systems have made this approach possible. Genes encoding storage proteins containing a more favorable amino acid balance, by and large, do not exist in the genomes of major crop plants. Furthermore, modification of native storage proteins has met with difficulty because of their instability, low level of expression, and limited host range. However, there has been some success in recent years in improving the content of single amino acids using this approach. For example, 2S methionine-rich Brazil nut albumin (18% methionine) has been used to enhance levels of seed protein methionine in canola. A chimeric gene regulated by a phaseolin promoter was fused to the 17-kDa Brazil nut albumin and expressed in transgenic canola plant seeds. The methionine-rich protein exhibited temporal regulation with significant accumulation of the protein late in development, thereby correlating with that of wild-type 11S-canola seed protein. There was a 33% increase in the methionine level, as well as a 4% increase in the total protein level. In the case of Brazil nut 2S albumin, the highly allergenic nature of the protein, however, renders it unsuitable for use in food plants. A possible alternative to the chimeric gene approach would be to design de novo a more nutritionally balanced protein that retains certain characteristics of the natural storage proteins of plants, yet contains all of the essential amino acids at their proper ratio for the feeding of humans and animals.

The biosynthesis of amino acids from simpler precursors is a process vital to all forms of life as these amino acids are the building blocks of proteins. Organisms differ markedly with respect to their ability to synthesize amino
In fact, virtually all members of the animal kingdom are incapable of manufacturing some amino acids. There are 20 common amino acids that are utilized in the fabrication of proteins and essential amino acids are those protein building blocks that cannot be synthesized by the animal. It is generally agreed that humans require 8 of the 20 common amino acids in their diet: isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine, to maintain good health. Protein malnutrition can usually be ascribed to a diet that is deficient in one or more of the essential amino acids. Therefore a nutritionally adequate diet must include a minimum daily consumption of these amino acids.

When diets are high in carbohydrates and low in protein, over a protracted period, essential amino acid deficiencies result. The name given to this undernourished condition is “kwashiorkor” which is an African word meaning “deposed child” (deposed from the mother’s breast by a newborn sibling). This debilitating and malnourished state, characterized by a bloated stomach and reddish-orange discolored hair, is more often found in children than in adults because of their greater need for essential amino acids during growth and development. In order for normal physical and mental maturation to occur, a daily source of essential amino acids is a requisite.

Essential amino acid content, or protein quality, is as important a feature of the diet as total protein quantity or total calorie intake.

Some foods, such as milk, eggs, and meat, have very high nutritional values because they contain a disproportionately high level of essential amino acids. As mentioned previously, many plants are notoriously deficient in essential amino acids. The amino acid composition of most plants is insufficient to sustain proper human growth and development. To rely solely on plants as a source of food (as so many people in developing countries must do) requires large intakes and mixtures of plant material to obtain all of the essential amino acids required to sustain life. To satisfy the minimum daily requirement of essential amino acids of a human child, a very unbalanced amount of plant foodstuffs are required as compared with the amounts necessary to consume from egg and beef (Table 1). As we know from experience, obtaining such essential amino acids from animal products creates an increasing demand on basic food crops such as corn, soybeans, and wheat. At this time, increases in animal production to meet future food needs are not viable options, at least through traditional methods.

*The values are what are necessary to consume in grams/day to achieve minimum daily requirement for all essential amino acids for a 10-year-old child. This assumes that the protein, in each foodstuff, is 100% bioavailable, and we know it is not, so these numbers should be increased to an even higher level.

**PRODUCTION OF NOVEL PROTEIN**

De novo artificial plant storage proteins have been designed to accomplish this nutritional goal. These proteins can be adjusted to accommodate any composition of essential amino acids desired for the consumption by animals and humans, based on any parent crop. Moreover, unlike many storage proteins found naturally in plants—that are only “partially” bioavailable to those consuming them—the proteins produced as a result of these designs are near 100% bioavailable. In collaboration with Dr. Marceline Egnin and Dr. C.S. Prakash, of Tuskegee University, we have introduced one of these artificial.
plant storage protein genes into sweet potatoes. Several years of field trials have been completed and small animal feeding studies have been conducted. The results of this work have been most promising. The roots of this transgenic plant T5 contain a more balanced amino acid composition provided by the new gene, as well as substantially higher levels of overall protein content[8] (Fig. 1). Thus we have within our grasp the capability of producing indigenous, edible plant foodstuffs and feedstuffs for humans and domesticated animals that would be efficient, cost-effective, and provide complete protein and essential amino acid sources; no supplementation with animal protein sources would be necessary. It is estimated that the total food or feed intake necessary to meet these daily needs could be reduced by more than 75% after this technology is implemented.

CONCLUSION

Improving the essential amino acid composition of basic food and feed crops, as well as increasing their overall protein content, can make a major contribution toward helping to meet the world’s future food needs. That advancement combined with conference of disease and stress resistance could result in a better-fed world in the future.

INTRODUCTION

Isolated plant protoplasts have several biotechnological applications, including their fusion to generate novel somatic hybrid and cybrid plants and the production of transgenic plants expressing specific characteristics. Normally, plant breeders rely upon sexual hybridization to combine useful genetic traits from different species or genera, but hybridization may be impeded by natural complex incompatibility barriers. The fusion of protoplasts isolated from somatic cells circumvents such barriers. Unique combinations of nuclear and organelar genomes generate novel germplasm; during protoplast fusion, there is no strict maternal inheritance of organelles, unlike in sexual hybridization.

FUSION OF ISOLATED PROTOPLASTS

Protoplast fusion can be induced chemically or electrically, or by a combination of these techniques, using small- or large-scale procedures. Plasma membranes of protoplasts destabilize during fusion, establishing cytoplasmic continuity between tightly adhering protoplasts. Polyethylene glycol (PEG) is a common fusogen, sometimes in combination with high pH and Ca²⁺.

Electrical fusion of protoplasts is more reproducible than chemical fusion and often gives greater fusion frequency. Versatile electrofusion instruments can be constructed. Prior to electrofusion, isolated protoplasts are suspended in a medium of low conductivity [e.g., mannitol with CaCl₂] to stabilize plasma membranes. Exposure of protoplasts to an alternating current of 0.5–2.0 MHz at 100–400 V cm⁻¹ induces protoplasts to align into “pearl chains” perpendicular to the electrodes; increasing the field strength induces close membrane-to-membrane contact. A subsequent direct current pulse of 10–200 micro-seconds and 500–2000 V cm⁻¹ coalesces adhering plasma membranes at the poles of the protoplasts. Protoplast fusion normally occurs about 10 minutes after electrical treatment.

NOVEL HYBRIDS AND CYBRIDS GENERATED BY PROTOPLAST FUSION

Symmetric nuclear hybrid plants resulting from fusion are generally rare, with most being asymmetric hybrids. Plant breeders often require the introgression of a limited number of chromosomes, parts of chromosomes, or only organelles (chloroplasts and/or mitochondria) from one species into another. Consequently, effort has focused on generating asymmetric nuclear hybrids and cytoplasmic hybrids (cybrids). Cybrids are those with a nuclear genome of a given genus or species (recipient) with plastids from the other partner, or, more rarely, a mixed population of plastids from the recipient and donor. Cybrids harbor a mitochondrial genome partly or totally from the recipient or the donor, or novel mitochondria following recombination of recipient–donor mitochondrial DNA.

Asymmetric hybrid production is stimulated by treatment, before fusion, of protoplasts of one partner with X or gamma irradiation and exposure of the protoplasts of the other parent to a metabolic inhibitor (e.g., iodoacetamide). Irradiation stimulates partial genome transfer, the irradiated and nondividing but metabolically active protoplasts overcoming the inability of inhibitor-treated protoplasts to undergo mitosis. Frequently, somatic hybrid plants resemble the partner used as the source of the inhibitor-treated protoplasts.

GAMETOSOMATIC HYBRIDIZATION

Transfer of genetic information into cultivated plants can be achieved by generating addition or substitution lines via...
the sexual production of generating triploids. Infrequently, triploids arise during the fusion of diploid protoplasts, as in Citrus. They can also be generated by fusing diploid with haploid protoplasts. The latter can be isolated from haploid plants.\[3\]

PRODUCTS OF PROTOPLAST FUSION: SELECTION OF SOMATIC HYBRID TISSUES AND PLANTS

Fusion of protoplasts of the same genetic composition generates homokaryons, producing plants with increased ploidy. In contrast, heterokaryons from the fusion of protoplasts of different genetic composition have application in plant improvement, as they contain the nuclei of both parentals, initially in a mixed cytoplasm. The selection of heterokaryon-derived tissues and somatic hybrid plants remains a difficult aspect of somatic hybridization. In some combinations, heterosis (hybrid vigor) results in heterokaryon-derived tissues developing first in culture. Such tissues can be selected manually prior to plant regeneration.

Micromanipulation is useful when parental protoplasts are morphologically distinct. For example, fusion of suspension cell protoplasts with green leaf protoplasts generates heterokaryons initially with colorless plastids in one half of their cytoplasm and chloroplasts in the other half. Fluorochromes and flow cytometry can also be used in heterokaryon identification. Hormone autotrophism has also been exploited for hybrid selection.\[4\] Complementation systems have been devised to select somatic hybrids. The most simple involves fusion of protoplasts of nonallelic albino mutants to generate hybrid cells that complement to chlorophyll proficiency in the light.

Auxotrophic mutants have been exploited in selection, the nitrate reductase deficiency of the nia-63 mutant of Nicotiana tabacum being complemented by the chlorate-resistant line (cnx-68). Protoplasts of the mutants fail to grow on nitrate-supplemented medium. However, somatic hybrid cells undergo complementation and can be selected on nitrate-containing medium. Antibiotic resistant cells are also useful in selection. Dominant antibiotic resistant genetic markers can be introduced by transforming parental cells prior to protoplast isolation.

In addition to antimetabolites being used to promote cybridization, such compounds that inhibit cell development have been exploited in hybrid selection. In the somatic hybridization of Lactuca sativa with the wild species Lactuca virosa, hybrids were selected by inactivation of L. sativa protoplasts with iodoacetamide, combined with the inability of L. virosa protoplasts to divide in culture.\[5\] Transformation to kanamycin resistance has also been combined with metabolic inhibition to select hybrid cells and plants.

CHARACTERIZATION OF SOMATIC HYBRID PLANTS

Characterization of plants generated by protoplast fusion necessitates morphological, cytological, and molecular analyses. Traits characteristic of both parents may be readily apparent in somatic hybrid plants, with leaves, flowers, and pigmentation being intermediate between those of both parents. In other cases, characteristics from one parent may be dominant.

Theoretically, plants regenerated by fusing two diploid somatic cell protoplasts should be tetraploid, which is the case in some combinations. However, plants with complete chromosome complements of both parents are generally rare. Hybrids often possess an asymmetric combination of parental chromosomes, following elimination of parts of genomes during culture.\[6\] The reasons for chromosome elimination are unclear. Some somatic hybrid plants are fertile; others may be sterile.\[7\] Cytological analyses of backcross progeny provide evidence of parental chromosomal behavior during mitosis and meiosis following introduction of somatic hybrids into breeding programs. Flow cytometry can estimate the ploidy of plants and provide a baseline for cytological analyses. DNA fingerprinting\[8\] permits detailed characterization of nuclear and organellar genomes of parental and somatic hybrid plants.

Organellar events are complex in somatic hybrids. Initially, heterokaryons contain a mixed population of organelles. Subsequently, plastids usually segregate, with those of one partner becoming dominant;\[7\] in some cases, the plastids of both partners persist in hybrids. Recombination of plastid DNA is rare. Analysis of ribulose biphosphate carboxylase–oxygenase, linked to the chloroplast DNA restriction enzyme profile, confirms the parental origin of chloroplasts in somatic hybrids. Recombination of mitochondrial DNA commonly generates “new” organelles, as evidenced by the restriction enzyme digestion patterns.\[7\] Importantly, DNA recombination in organelles increases genetic diversity arising from protoplast fusion.

Examples exist of the transfer of agronomical traits by protoplast fusion. Considerable effort has focused on the Solanaceae, such as potato and tobacco, together with the Brassicaceae. An excellent example is provided by studies in which protoplasts of Solanum tuberosum were fused with those of the wild potato, Solanum bulbocastanum,\[9\] generating hybrids having improved resistance to late blight. Importantly, this resistance was transferred to other breeding lines by back-crossing.
TRANSFORMATION OF ISOLATED PROTOPLASTS BY DNA UPTAKE

Induction of DNA Uptake

The induction of transient pores in the plasma membrane permits uptake of DNA by chemical and/or physical procedures. Several agents induce DNA uptake into protoplasts, including salt solutions with Ca$^{2+}$ at high pH and PEG. Electroporation, using short duration, high-voltage electrical pulses, often with PEG, is also used for DNA uptake into protoplasts. DNA has also been microinjected into protoplasts. PEG and electroporation remain the most successful procedures for protoplast transformation, even though the frequency is low and, at best, only about 1 in $10^4$ protoplasts develops into transformed tissues. Protoplasts can be transformed simultaneously with more than one gene, the genes being either on the same or separate vectors.

Factors Influencing Protoplast Transformation

Parameters have been identified that influence protoplast transformation. The stage in the cell cycle is important, efficiency being higher when protoplasts are in the S or M phases. Consequently, it is beneficial to synchronize cells prior to or immediately following protoplast isolation. Heat shock or irradiation of protoplasts before DNA uptake also stimulates transformation, irradiation probably increasing recombination of genomic DNA with incoming DNA or initiating repair mechanisms that favor DNA integration. Complex integration patterns have been observed following DNA uptake into protoplasts.

MISCELLANEOUS STUDIES WITH PROTOPLASTS

Isolated protoplasts have also featured in physiological, ultrastructural, and genetic studies. Their development into colonies of single cell origin has been exploited to isolate clonal lines and plants, including those for increased secondary product synthesis. Exposure of isolated protoplasts to mutagenic agents or irradiation permits the induction and selection of mutants. Protoplasts take up macromolecules, which has been exploited in studies of endocytosis and virus infection and replication. The osmotic fragility of isolated protoplasts permits their controlled lysis for isolating cell components. In physiological studies, isolated vacuoles have been used to investigate sugar accumulation; protoplasts from barley aleurone cells contain protein storage vacuoles and a lysosome-like organelle, designated the secondary vacuole. Protoplasts are ideal for studying ion transport and regulation of the osmotic balance of cells.

Light-induced proton pumping has been investigated in guard cell protoplasts. Other studies have focussed on cell fusion and metabolism in microgravity, elicitor binding sites, binding of fungal phytotoxins to plasma membranes, and auxin accumulation and metabolism. Protoplasts have also provided unique material for studying cell wall synthesis and the role of microtubules during cell development. Protoplasts from totipotent cells, are useful for assessing the effects of pharmaceuticals, food additives, cosmetics, and agrochemicals on plant cells, whole plants, and their progeny over seed generations.

INTRODUCTION

Plant protoplasts represent the living contents of cells, each bounded by a plasma membrane and enclosed by a cell wall. The plasma membrane is involved in wall synthesis. Consequently, there is usually intimate contact between these two structures. However, when cells are stressed osmotically, their plasma membranes contract away from their surrounding walls. Subsequent removal of the walls enclosing plasmolyzed protoplasts enables the latter to be isolated as spherical, osmotically fragile, "naked" cells. The isolation of large populations of protoplasts from a range of plants is now routine. Such isolated protoplasts are ideal for studies of cell development, physiology, and cytogenetics. When cultured in the laboratory, isolated protoplasts undergo wall resynthesis and mitotic division. Protoplast-derived cells may express their totipotency, regenerating into fertile plants under the correct physiological and physical stimuli. This feature, unique to plant cells, is exploited in genetic manipulation through somatic hybridization and cybridization, both involving protoplast fusion, and transformation by direct uptake of foreign DNA.

ISOLATION OF PLANT PROTOPLASTS

The physiological status and age of tissues is crucial for the isolation of viable protoplasts. While leaves of glasshouse-grown plants are a convenient source of protoplasts, seasonal variation in illumination, temperature, and humidity may necessitate the use of environmental cabinets to ensure uniformity of material. Generally, cultured shoots and in vitro grown seedlings are more uniform as source material than pot-grown plants. Haploid pollen tetrads and mature pollen will release protoplasts; cell suspensions are convenient and frequently exploited as a source of protoplasts.\(^1\)

Combinations of commercially available cellulase, hemicellulase, and pectinase enzymes are used to release large populations of protoplasts. The cell wall composition of source tissues dictates the enzyme mixture required. Consequently, enzyme concentrations and conditions must be determined empirically for protoplast isolation from specific plant tissues.\(^2\) The time of enzyme digestion, usually at 25–28°C, may be of short duration (e.g., 4–6 hours) or overnight (12–20 hours). Removal of the lower epidermis or dissection of leaves into thin strips facilitates tissue digestion and protoplast release. Preconditioning of donor plants or explants by exposure to reduced illumination or preculture of donor explants on suitable media may increase protoplast yield and viability.

Passage of enzyme-protoplast mixtures through sieves of suitable pore sizes following enzyme incubation removes undigested cells. Gentle centrifugation (e.g., 100 \(\times\) g; 10 min) through a suitable osmoticum [e.g., 13% (w/v) mannitol] generally pellets the protoplasts, leaving fine debris in suspension. Mixing protoplasts with 21% (w/v) sucrose in a salts solution,\(^3\) or with a solution of Percoll or Ficoll, followed by centrifugation, causes protoplasts of many species to float, facilitating their collection.

CULTURE OF ISOLATED PLANT PROTOPLASTS

Nutritional Requirements of Protoplasts: Culture Media

Protoplasts commence wall regeneration within hours of being introduced into culture. However, they require osmotic protection until they have regenerated a new primary wall of sufficient strength to counteract the turgor pressure exerted by the living cytoplasm/vacuoles.
Many media have been reported for protoplast culture. The nutrient-rich KM-type formulations\[4\] are beneficial for culture of protoplasts at low densities; other media are often based on the well-tested MS\[5\] and B5\[6\] formulations. Ammonium ions are detrimental to some protoplasts, particularly those of woody species. Sucrose is the most common carbon source, although glucose may act as both a carbon source and osmotic stabilizer. Maltose stimulates shoot regeneration from protoplast-derived cells, especially in cereals.\[7\] Most protoplasts require one or more auxins or cytokinins in the culture medium to sustain mitotic division.

**Systems for Protoplast Culture**

Incubation of isolated protoplasts in liquid medium in Petri dishes or in a shallow liquid layer overlaying semisolidified medium are simple methods of culture. The inclusion of a filter paper at the interface between the liquid and semisolid phases may stimulate cell colony formation. Isolated protoplasts can also be embedded in semisolidified media. Several gelling agents are available, with agarose often enhancing protoplast plating efficiencies (calculated as the percentage of the protoplasts originally plated that develop into cell colonies), compared with agar. Semisolid medium containing the protoplasts may be dispensed as layers or droplets (the latter about 100 μl in volume) in Petri dishes. Alginate is a useful gelling agent for heat-sensitive protoplasts. Following suspension of the protoplasts, the alginate-culture medium mixture is semisolidified by pouring the warm mixture in which the protoplasts are suspended over an agar layer containing Ca\(^{2+}\) or by gently dropping the molten medium into a solution of such ions.

**Plating Density and Nurse Cells**

The density at which protoplasts are plated in the culture medium is crucial for cell colony formation. Generally, the optimum plating density is 5 \times 10^2–1.0 \times 10^6 ml\(^{-1}\). At greater densities, protoplast-derived cells often fail to undergo sustained mitotic division because of rapid depletion of nutrients from the medium. Protoplasts also fail to grow when plated below a minimum density. Medium previously “conditioned” by supporting the culture of actively dividing cells for a limited period, will stimulate the growth of isolated protoplasts. “Nurse” cells are often employed to promote division of protoplasts in culture.\[7\] When using nurse cultures, the isolated protoplasts can be embedded in a semisolid layer, suspended in a thin layer of liquid medium, or spread in a liquid layer on a cellulose nitrate membrane, overlaying the semisolid medium containing the nurse cells.

**INNOVATIVE APPROACHES TO PROTOPLAST CULTURE**

**Chemical Supplements for Culture Media:**

**Surfactants and Antibiotics**

Some antibiotics (e.g., cefotaxime) stimulate protoplast division, such compounds being thought to be metabolized to growth regulator–like molecule(s). Supplementation of medium with the nonionic, surfactant Pluronic\[8\] F-68, increases the plating efficiency of protoplasts in culture. Surfactants may increase the permeability of plasma membranes, stimulating uptake of nutrients from the culture medium into protoplasts and protoplast-derived cells.\[8\]

**Manipulation of Respiratory Gases**

Gassing of vessels with oxygen after introducing protoplasts into the culture medium increases the plating efficiency of protoplasts of jute and rice. A further novel approach for regulating the supply of respiratory gases to cultured protoplasts involves the use of inert, chemically stable perfluorocarbon (PFC) liquids.\[9\] Such compounds dissolve large volumes of respiratory gases and have been exploited in animal systems as oxygenation fluids.\[10\] PFC liquids, being about twice as dense as water, form a distinct layer beneath aqueous culture media. Consequently, protoplasts and protoplast-derived cells can be cultured at the interface between the lower PFC layer and the overlaying aqueous medium. Experiments revealed that protoplasts in such systems exhibited increased superoxide dismutase activity associated with oxygen detoxification. Other regulators of respiratory gases, notably chemically modified haemoglobin solutions, may also stimulate the growth of protoplasts in culture. Supplementation of culture media with commercial bovine haemoglobin solution (Erythrogen\[TM\]) significantly increased the plating efficiency of rice protoplasts, compared to untreated controls.\[11\]

**Physical Methods to Stimulate Protoplast Growth**

Physical parameters have been shown to stimulate protoplast growth, including the use of cellulose nitrate filter
membranes (0.2 μm pore size) at the liquid/semisolid medium interface, often in conjunction with nurse cells in the underlying semisolid medium. Insertion of glass rods vertically into semisolid agarose medium stimulated mitotic division of cassava leaf protoplasts in the overlying liquid medium, the protoplasts probably receiving increased aeration where they aggregate in the liquid menisci around the glass rods. Electrical currents, both low and high voltage, also stimulate mitotic division and cell colony formation from protoplasts of many species.

PLANT REGENERATION FROM PROTOPLAST-DERIVED TISSUES

The induction and sustaining of plant regeneration in protoplast-derived tissues by different pathways of morphogenesis (organogenesis; somatic embryogenesis) is dependent, in part, upon the culture conditions, in particular, the composition of the culture medium, and the inherent totipotency of the donor species. Plant regeneration, via organogenesis, has been reported to occur for more than 70% of those species capable of regenerating plants from protoplast-derived tissues, most notably members of the Compositae, Cruciferae, Leguminosae, and Solanaceae. In contrast, plant regeneration from protoplast-derived tissues via somatic embryogenesis is restricted predominantly to members of the Curcurbitaceae, Gramineae, Leguminosae, Rutaceae, and Umbelliferae. In a limited number of genera, protoplasts may develop directly into somatic embryos through early polar growth of their derived cells, as in Medicago, Asparagus, and Persea.

CONCLUSION

During the last 40 years, considerable progress has been made in regenerating plants from protoplast-derived tissues of an increasing number of genera and species, driven by a need for regeneration as a platform for many aspects of biotechnology. It is interesting to note that it is only recently that protoplast-to-plant systems have been developed for specific genera, an example being provided by Sorghum, in which the establishment of such a protoplast-to-plant system required nearly 20 years of on-going research. An extensive literature is directed to plant regeneration from isolated protoplasts. The expression of totipotency from protoplast-derived tissues remains an absolute requirement for the multifaceted applications of somatic cell technologies involving protoplasts, such as somatic hybridization, cybridization, and direct DNA uptake, in plant genetic improvement programs. The relevance of these applications are discussed elsewhere in this volume.

INTRODUCTION

Domestication of many of today’s main food crops occurred approximately 10,000 years ago with the beginning of agriculture. It has led to the selection by farmers of a wide range of morphological and physiological traits that distinguish domesticated crops from their wild ancestors. These characteristics are collectively referred to as the domestication syndrome and include changes in plant architecture (e.g., apical dominance in maize), gigantism in the consumed portion of the plant (e.g., fruit size in tomato and eggplant), and reduced seed dispersal (i.e., nonshattering or nondehiscence, as in the common bean, sunflower, and cereals). Many investigations based on multidisciplinary approaches—such as genetic, archaeological, and phytogeographical analyses—have succeeded in identifying progenitor species and centers of domestication. However, the genetic and molecular bases of morphological evolution in plants under domestication are largely unknown.

Advances in genome mapping, which have resulted in high-density molecular-marker linkage maps in most crops, have provided tools for dissecting the genetic basis underlying complex traits into their individual components, i.e., their quantitative trait locus (QTL). This method relies on the frequent ability to cross the crop and its wild progenitor. It enables the characterization of genetic differences in terms of the number and chromosomal location of the genes as well as quantitative estimates of the kind and amount of genetic effects associated with individual loci. Recent studies have analyzed the genetics of the domestication syndrome of crops belonging to diverse families.

GENETIC BASIS AND ORGANIZATION OF THE DOMESTICATION SYNDROME

Many quantitative genetic analyses have focused on individual traits that are related to domestication but comprehensive analyses of the inheritance of the domestication syndrome[1] as a whole are scarce.

Major vs. Minor Genes

Research has revealed that numerous traits that distinguish crop plants from their wild relatives are often controlled by a relatively small number of loci with effects of unequal magnitude.

Many qualitative traits are controlled by one Mendelian locus such as seed shattering in sorghum[2] and pearl millet.[3] But even the traits that are usually considered as exhibiting quantitative inheritance involve few QTLs of large effect plus others of more modest effect. The genetic study of an F2 population derived from a cross of maize (Zea mays ssp. mays) and its wild progenitor, teosinte (Z. mays ssp. parviglumis),[4] revealed that the domestication traits are controlled primarily by five chromosomal segments (Table 1). One of the major QTLs, tbl (teosinte branched 1), conditions the dramatic alteration in plant architecture from a multistemmed, branched plant to the single-stemmed plant most people are familiar with. Similarly, in common bean, seed dispersal (pod dehiscence), seed dormancy, and photoperiod sensitivity are all determined by a few loci with effects of large magnitude.[5] In eggplant, most of the dramatic phenotypic differences in fruit weight, shape, color, and plant prickliness that distinguish domesticated eggplant,
Solanum melongena, from its wild relative, *S. linnaeanum*, could be attributed to six loci with major effects. On this basis, early domestication is most likely to have been a process involving major genes, while subsequent changes may have occurred by the accumulation of minor mutations. Some domestication traits result from the loss of wild-type function and are associated with recessive mutations. However, mutations altering gene regulation are also reported (discussed later).

**Clustered Distribution of QTLs**

Another interesting feature of the inheritance of domestication traits in crop plants is that the loci for such traits are frequently clustered in a few chromosomal regions (Table 1). This pattern of genetic correlations across traits due to linkage has been documented in some cases of domestications (Table 1). For example, in common bean, sunflower, and maize, QTLs underlying domestication traits are largely restricted to three and five genomic regions, respectively. In pearl millet, two regions of the genome control most of the key morphological differences of the spike and spikelet, including seed shattering. Each of the segments identified has an effect on related but also unrelated traits, suggesting that they could carry either a single mutation with pleiotropic effects or several mutations in linked genes. Linkage among domestication QTL is predicted to evolve under strong selection, especially in allogamous species. Eggplant is a predominantly self-pollinated crop and does not provide strong evidence for the colocalization of domestication syndrome traits.

INDEPENDENT SELECTION OF ORTHOLOGOUS REGIONS UNDER DOMESTICATION?

Comparative genetic mapping provides insights into the evolution of genome organization within the species investigated. A framework of common markers provides a basis for evaluating the correspondence between the locations of genes that confer common phenotypes. Many investigations have highlighted the preservation of the basic gene order, especially across grass species. Because similar traits have been selected during the domestication of crops belonging to the same family (e.g., Poaceae or Solanaceae), a common set of loci may also have been selected under domestication. The initial report of orthologous QTL noted that a genomic region that had the greatest effect on seed weight in mung bean and cowpea spanned the same restricted fragment length polymorphism (RFLP) markers in the same linkage order in both species. Later works showed that pea and soybean also contained this conserved genomic region (Table 2). Another study [2] described the comparative molecular analysis of QTLs associated with domestication of three crops, *Sorghum*, *Oryza*, and *Zea*, each on a different continent. Correspondence was evaluated among QTLs involved in sensitivity to photoperiod, shattering, and increased seed size. Genes/QTLs were found to correspond far more often than would be expected to occur by chance, suggesting that orthologous genes (i.e., homologous genes that trace back to a common ancestral gene as a result of speciation, so that the history of the genes reflects the history of the species) may be involved in the evolution of these phenotypes. In similar manner, comparison of the genomic locations of the eggplant fruit weight, fruit shape, and color QTL with the positions of similar loci in tomato, potato, and pepper revealed that 40% of the different loci have putative orthologous counterparts in at least one of these other crop species. [6]

Overall, the results suggest that domestication within each family has been driven by mutations in a very limited number of homologous loci that have been conserved throughout the evolution of the different species. Correspondence in location of QTLs in different taxa does not prove identity between the underlying genes, but it does suggest the identity of some of them.

FROM MORPHOLOGY EVOLUTION TO MOLECULAR EVOLUTION

Plant domestication offers a powerful system for studying the genetic and developmental basis of morphological evolution. Cloning the genes that largely control the differences between wild and domesticated plants provides the opportunity to examine the effects of selection on domestication genes at molecular and physiological levels, identify characters that are relevant for future crop improvement, and infer the history of domestication. The discovery of loci such as *tb1* [11] in maize or *fw2.2* [12] in tomato represented cases in which the evolution of better adapted phenotype was largely governed by a single locus, and the genes underlying each locus were subsequently identified and analyzed.

In tomato, a QTL, *fw2.2* changes fruit weight by up to 30% and appears to have been responsible for a key transition during tomato domestication. By applying a map-based approach, the gene responsible for the QTL was identified: *ORFX*. [12] This gene has a sequence suggesting structural similarity to the human oncogene c-H-ras p21. Alterations in fruit size, imparted by *fw2.2* alleles, are most likely due to changes in upstream regulatory sequences rather than in the sequence and structure of the encoded protein. The large- and small-fruited alleles differ in the timing of *fw2.2* transcription (heterochronic allelic variation) by approximately 1 week and in total transcript level. [13] Moreover, these differences are associated with concomitant changes in mitotic activity and are sufficient to cause a major change in final fruit mass. The large-fruit allele of *fw2.2* arose in wild populations long before being fixed in most domesticated tomatoes. [14] However, despite the fact that this allele was likely a target of selection during domestication, it has not evolved at distinguishably different rates in domesticated and wild tomatoes.

The most thoroughly analyzed domestication gene is *teosinte branched 1* (*tb1*) in maize. It was shown to correspond to a QTL involved in apical dominance. During

---

**Fig. 1** Predicted structure of *teosinte branched 1* (*tb1*) and analysis of polymorphism (π) in maize and teosinte. (From Ref. 11.)
development, *tb1* acts as a repressor of axillary branch growth in those organs in which its RNA messenger accumulates. The difference in mRNA accumulation in between maize and teosinte alleles suggests that the evolutionary switch involved changes in the regulatory regions of *tb1*. Indeed, population–genetic analysis of nucleotide polymorphism in *tb1* from a diverse sample of maize and teosinte indicates that a strong selective sweep has occurred during domestication in the 5′ NTR region of the gene but not in its coding region (Fig. 1). It was also inferred that the process of domestication could have taken at least several hundred years to bring the maize allele of *tb1* to fixation.

**CONCLUSION**

The archaeological record indicates that the domestication process of a crop, once initiated, may have been rapid, possibly encompassing only the few hundred years needed to fix relevant alleles of key genes and of their modifiers. A better understanding of the genetic differences between wild plants and domesticated crops adds important facets to the continuing debate on the origin of agriculture and the societies to which it gave rise. The study of crop domestication is also an opportunity for scientists who seek to understand the genetic basis of plant growth and development. The molecular dissection of complex traits through breeding approaches, coupled with the parallel analysis of gene expression, promises to add much to our understanding of the relationships between molecular polymorphism and phenotypic diversity and the genetic basis and evolutionary dynamics of adaptation.

Quantitative Trait Locus Mapping of Agronomic Traits

Mark E. Sorrells
Department of Plant Breeding and Genetics, Cornell University, Ithaca, New York, U.S.A.

INTRODUCTION

A quantitative trait locus (QTL), also used for the plural, loci, is the location of a gene(s) that affects a trait that is measured on a quantitative scale. QTL mapping has its basis in quantitative genetics theory but uses molecular genetics to “Mendelize” quantitative traits. The realization in the early 1900s that discrete Mendelian inheritance could not explain the inheritance of a large number of traits, resulted in numerous debates and theories that spawned a large subdiscipline devoted to understanding the genetic control of traits that exhibit a continuous distribution of phenotypes. The breakdown of discrete classes of phenotypes is caused by both multigenic inheritance and influence of non-genetic factors (environment). Examples of quantitative traits include plant height, grain yield, seed size, lodging resistance, and many other agronomic traits. Thus, mapping a QTL is not as simple as mapping a single gene that affects a qualitative trait (such as flower color). Linkage between a genetic marker and a QTL was first demonstrated by Sax[1] in a study that reported an association between bean seed coat color and seed weight. The major limitations to earlier studies using visible markers were the number of useful, discrete markers and their poor distribution in the genome. Those limitations were alleviated in the early 1980s by the advent of isozyme and molecular markers such as restriction fragment length polymorphisms. The feasibility of constructing saturated genome linkage maps paved the way for the molecular dissection of complex, quantitative traits. The purposes of QTL mapping are to elucidate the genetic control of a trait of interest, identify molecular markers for marker-assisted selection, and characterize the genes controlling traits of agronomic importance, most of which are quantitative.

GENERAL QTL ANALYSIS REQUIREMENTS AND STRATEGY

The essential requirements for QTL mapping are a complete (saturated) molecular marker linkage map, a population segregating for markers and traits of interest, linkage disequilibrium (LD), and phenotypic data for traits of interest. The general strategy used in QTL mapping is to first classify progeny by marker genotype, followed by a comparison of phenotypic means between marker classes to determine if the difference is statistically significant, and then to calculate the difference between the means for an estimate of the QTL effect. A QTL experiment is usually designed to maximize the amount of genetic variation in the mapping population to increase the statistical power for mapping QTL, and to provide genetic information such as linkage phases and recombination of markers. A number of different kinds of QTL analyses have been developed, some of which take advantage of the data structure to improve the accuracy of the analyses.

Single-marker or single-point analysis is based on analysis of variance (ANOVA), t-test, or regression of an individual marker locus and the phenotypic data for the population. Association of a marker and trait can also be resolved using the likelihood approach by finding the joint distribution of marker genotypes and possible QTL genotypes.[2] Because the exact location of a QTL may not coincide with a marker, single-marker tests are limited by the confounding of QTL genotypic means and QTL locations resulting in inaccurate estimates of QTL effects and low statistical power at low marker densities.

Simple interval mapping (SIM) can more accurately estimate the QTL location using either maximum likelihood,[2] or regression analyses (less computationally intensive).[3] SIM analysis uses information from markers flanking an interval to estimate the peak of the QTL (Fig. 1). Additive and dominance effects can be estimated using a three-genotype system for F2 populations by using multiple linear regression.[4]

CIM[5,6] is a combination of SIM and multiple linear regression where background markers are used to reduce the residual genetic effects. When multiple QTL segregate, sampling error about the target QTL may be inflated by other QTL. CIM fits parameters for a target QTL in one interval while simultaneously fitting partial regression coefficients for “background markers” to account for variance caused by non-target QTL (QTL not being analyzed). Genetic variance caused by QTL other than the target is absorbed by the regression coefficients of the background markers. Compared to SIM, CIM produces more precise estimates of the location of the QTL and can often resolve closely linked QTL (Fig. 1). The choice of background
markers is somewhat arbitrary, although stepwise regression is often used.

Association mapping (AM) differs substantially from the standard QTL analysis methods described above in terms of the populations used and the statistical analysis methods. In contrast to methods employing a biparental cross population, AM uses a collection of diverse genotypes that exhibit varying degrees of genetic relationship. The association between a trait and a marker depends on the degree of LD in the collection of genotypes used and the distance from the marker to the functional polymorphism. Consequently, in germplasm sets where LD is low, many closely spaced markers are required for whole genome coverage, and AM is typically restricted to regions of putative QTL based on a priori knowledge. AM is complementary to standard QTL analysis because information on the locations of QTL can be used with AM to fine map the QTL and assess the effects of multiple alleles in a collection of germplasm accessions.

Types of Populations

There have been QTL analysis procedures developed for a wide range of segregating populations including inbred-derived populations and outcrossing populations. F3 families derived from individual F2s are frequently used for species that tolerate some degree of inbreeding. They are quick and easy to generate and very efficient for estimating additive and dominant gene action. The primary limitation is often the amount of seed available for replicating genotypes for evaluation in multiple replicates and environments. There is also limited genetic recombination resulting in high LD and large QTL intervals. A backcross population is especially useful when one of the parents is unadapted or has traits such as seed shattering that interfere with evaluation of traits of interest. One advantage is that the products can be integrated into a breeding program. Backcross populations are limited in seed supply, difficult to generate in some species, and cannot be used to estimate gene action (no recessive QTL alleles). Doubled haploid lines are moderately easy and quick to generate for some species but are not available for others. The main advantage is that the lines are true breeding and therefore can be used for evaluation in many environments. Dominant gene action cannot be estimated and with only one meiosis, genetic recombination is very limited. Recombinant inbred lines (RILs) are true breeding, relatively inexpensive, and easy to generate for many species. Also there is generally about twice as much genetic recombination as for doubled haploids. Highly outcrossing species that cannot be easily inbred include species such as potato, alfalfa, and sugarcane. Specific genotypes of these species are usually propagated by cloning. To generate a segregating population, two clones are crossed to generate a progeny that is already segregating and does not require additional inbreeding to construct a map. In fact, because we are sampling gametes from two different individuals (instead of one F1 as described above for inbreeding) two separate marker maps are constructed, one for each parent that are later merged. For polyploids, markers that are polymorphic for loci on more than one chromosome can often be used to identify homologous groups. This type of population is quick and easy to generate and is very efficient for estimating additive and dominant gene action. For polyploids, allele detection for all homologous chromosomes is difficult and replication requires clonal propagation. Full and half sib families can be easy and quick to generate in some species. Such family structures can be efficient for estimating gene action provided there is adequate genetic variation and map resolution; however, seed supply may be limiting for some species.

QTL Mapping Using Distributional Extremes

When one is interested in only one quantitative trait in a cross, substantial time and expense can be saved by determining marker genotypes only for those progeny, which have extreme values, both high and low, for the trait. Most of the useful mapping information can be obtained from the 10–20% of progeny that have the highest trait values and the 10–20%, which have the lowest trait values. This practice may be called “selective genotyping” and is based on the idea that once a QTL has been mapped to a particular interval, only recombinant individuals are informative and contribute to greater mapping accuracy. Unfortunately, this concept is less likely to apply to pooling DNA from the extreme genotypes. While DNA pooling has been successfully applied to mapping genes that control nearly all the variance in a trait, there has been less success in applying this technique to QTL.

Fig. 1 A comparison of likelihood ratio (LR) plots from SIM and Composite interval mapping (CIM) illustrating the improved resolution possible by using background markers to minimize residual effects. (View this art in color at www.informaworld.com.)
**Statistical Considerations**

Test statistics are an attempt to quantify Type I (probability that a QTL declared to be significant does not exist) and Type II (probability that a real QTL is not declared significant) error rates. The t-test or F-value is often used for single-marker analyses and the $R^2$ value reflects the portion of the phenotypic variance explained by that marker. For the maximum likelihood analysis, a likelihood ratio statistic (LOD) of the null vs. the alternative hypothesis is used (Lander and Botstein) (Fig. 1). The LOD threshold for significance is a function of marker density and genome size. Power refers to the probability of detecting a QTL of known magnitude, given experimental parameters that affect the frequency of false positive associations such as population size and map characteristics (Fig. 2). Depending on genome size and statistical test used, for many maps, LOD 3.3 corresponds to an experiment-wise Type I error of 5%, alpha = 0.001. Because random error can inflate the test statistic, permutation was proposed to empirically establish significance without assumptions.[10] Permutation analysis randomizes the relationship between genotype and phenotype thousands of times, each time reanalyzing the data, to establish an error rate for each variable in each experiment. Simulations may produce conclusions that are specific only to the experiments analyzed owing in part to the distribution of markers in the genome.

Because most QTL are affected by the environment, QTL effects will vary by environment, resulting in QTL x environment interactions. Estimating this interaction is important to breeders and geneticists because it determines the predictability of the QTL effect from one environment to the next. Currently, multiple interval mapping is widely used. This analysis is based on a multiple QTL model that improves the precision and power of QTL mapping and allows for the identification of epistatic interactions, genotypic values, and heritabilities.[11]

Trait dissection or QTL analysis of components of complex traits is often used because of the complexity of many quantitative traits. For example, grain yield may be broken down into seed size, seed number per spike, number of spikes per unit area, disease resistance, duration of seed filling, etc. Such traits may have higher heritability or be easier to measure.

**Software**

A large number of commercial and freely available computer programs are available, which implement

![Population Size for QTL detection](https://www.informaworld.com)

Fig. 2  Relationship between linkage map marker density, $r^2$ for a QTL, and population size. The population size necessary was calculated by $n_{B_1} = \left( \frac{1 - r^2_{B_1}}{r^2_{B_1}} \right) \left( \frac{z_{1-\alpha}(\sqrt{1-r^2_{B_1}})}{z_{1-\beta}} + z_{1-\beta} \right)^2$ where $\alpha = 0.05$ and $\beta = 0.10$. (Adapted from Ref.[10].) *(View this art in color at www.informaworld.com.)*
one or more of the analyses mentioned above. Those include MapMakerQTL, MAPQTL, QTL Cartographer, MapManager QTX, and Qgene, just to mention a few. A computer program called TASSEL is freely available for AM.

CONCLUSIONS

Molecular markers and QTL analysis have revolutionized our understanding of the genetics of agronomic traits. These tools are critical for elucidating the genetic control of a trait of interest, marker-assisted selection, and gene cloning. A wide variety of populations and analysis methods have been developed to identify the number and location of QTL in agronomic species.

Ronald L. Phillips
University of Minnesota, St. Paul, Minnesota, U.S.A.

INTRODUCTION

Radiation hybrid maps are physical maps of genomes that provide an alternative to traditional genetic maps. These radiation hybrid maps have two important advantages over genetic maps. First, distances on a radiation hybrid map are determined by the frequency of radiation-induced breaks between markers. The distribution of breaks is believed to be random; therefore, distances calculated along a radiation hybrid map are proportional to physical distances. Genetic crossovers (used to determine genetic distances) are not randomly distributed, making it impossible to predict physical distances between markers from genetic maps in maize and many other plant species. Second, any sequence of interest is readily placed on a radiation hybrid map. In contrast, only polymorphic markers can be mapped on a genetic map. Individual markers for genetic mapping must have detectable differences between the parents of the mapping population. A monomorphic marker—one for which there is no apparent difference in the population—cannot be mapped. High-quality maps produced by radiation hybrid mapping have proven their worth in the human genome project, with over 30,000 sequences mapped. It is anticipated that radiation hybrid maps will be similarly useful in plants.

RADIATION HYBRID MAPPING

Radiation hybrid (RH) mapping was developed in the 1970s as a tool for mapping genes in humans. Improved analytical and molecular methods allowed Cox and co-workers to develop RH mapping into an effective tool.[1] This work spurred further developments, and RH maps are now under construction or completed for the human genome and a number of other species.[2,3] Current information about projects may be obtained from the Radiation Hybrid Mapping Page at http://compgen.rutgers.edu/rhmap/. One reason for the popularity of radiation hybrid maps is that they are physical maps. This property makes RH maps particularly useful in assisting the construction of bacterial artificial chromosome (BAC) or yeast artificial chromosome (YAC) contigs. In this role RH maps are contributing to genome sequencing projects. Map information has other uses; with the degree of gene, chromosome, and genome duplication in plants, positional information is vital for identifying candidate sequences.

In the widely used whole genome approach (WG-RH), a donor cell line from the species being mapped is irradiated to kill the cells and fragment the chromosomes. Then donor cells are fused with recipient cells. Some of the chromosome fragments become integrated into the host chromosomes or are retained as a new chromosome consisting of numerous fragments joined together. Each radiation hybrid cell line retains between 10% and 50% of the donor genome, and a group of approximately 100 cell lines forms a mapping population or panel.[3,4]

The likelihood that a break will occur between markers is directly proportional to the physical distance between them at a given radiation dose. This property of radiation hybrid lines underlies the methodologies used to analyze RH mapping data. Plus-minus PCR assays are used to detect the presence of markers in RH lines; polymorphic markers are not required for mapping. These data are analyzed by one of several approaches to produce an RH map. Distances between markers are expressed in centirays (cR). One cR represents a 1% frequency of breakage between two markers at a specific radiation dose. Breaks are assumed to be distributed randomly, and this makes it possible to relate centirays to kilobases of DNA. Examples of methods used to analyze RH mapping data may be found in Barrett[4] and in references contained in Walter and Goodfellow.[2] Computer programs for analysis of RH data may be accessed through the Radiation Hybrid Mapping Page.

Whole plants instead of cell lines may be used to create RH lines.[5] The starting materials here were oat-maize addition lines containing a single maize chromosome in an oat background. RH lines were selected from among the progeny of irradiated oat-maize addition lines (Fig. 1). RH lines produced by this method have different characteristics from WG-RH lines. First, most RH lines
produced from addition lines appear to be stable (personal communication), whereas cell culture lines produced by the WG-RH approach are unstable. Second, lines produced from oat-maize addition lines have fewer chromosome breaks than do WG-RH lines. The need to maintain seed viability places limits on the level of chromosome breakage in oat-maize RH lines. A single contiguous fragment may be retained in these RH lines. With a few of these lines, markers may be quickly localized to a chromosome segment. WG-RH lines retain many small fragments. Many WG-RH lines are required to map a marker, but the mapping can be very precise. The pattern of chromosome breaks in RH lines produced from addition lines may limit the practical resolution of these RH maps.

No WG-RH map from a plant has yet been reported. A variation of the WG-RH protocol is being developed in barley, where barley donor protoplasts are irradiated and

![Fig. 1](image-url) Principal steps for development and use of oat-maize RH lines. A set of oat plants with a monosomic addition of one maize chromosome is produced from an oat x maize interspecies hybrid. Monosomic seed are irradiated to induce breaks in the maize chromosome. The maize chromosome fragments are transmitted either through their association with the maize centromere or through translocation to a centric oat chromosome fragment. In the segregating offspring, plant genotypes are screened for breaks by molecular and cytological means. The example shows two different oat-maize translocation plants that define three maize chromosome segments. (View this art in color at [www.dekker.com](http://www.dekker.com).)
fused with tobacco recipient protoplasts.[6] Results suggest that RH mapping can become a useful tool in plants.

OTHER PHYSICAL MAPPING APPROACHES

RH mapping represents only one approach to developing physical maps. Alien addition lines, such as the oat-maize addition lines, have been used for locating markers to chromosomes in several species. Aneuploid lines, nullisomic lines, and B–A translocation lines are also used to locate genes to chromosomes or chromosome arms. Examples of these systems are discussed elsewhere in this encyclopedia. Second, systems that fractionate chromosomes have been exploited to place sequences in sub-chromosome regions. Notable among this work are the wheat deletion stocks where hundreds of lines have been produced with cytologically characterized deletions.[7] Work is ongoing to place molecular markers on these materials. A third approach is molecular cytogenetic maps. These are described in another article. Interest in plant genomics has fostered a desire for better physical maps of plant genomes. There are now several methods to make physical maps. Each approach has its own strengths and weaknesses for resolution, ease of development, and utility in particular species and applications.

STABLE RADIATION HYBRID LINES HAVE MANY USES

The primary reason for producing the oat-maize radiation hybrid lines was to develop a physical mapping system for maize. But mapping is not the only use for these materials. The stability of these materials allows other uses, three descriptions of which follow. First, chromosome pairing has been studied.[8] Using the addition lines, the single pair of maize chromosomes can be specifically labeled and followed through meiosis in the addition lines. This greatly simplifies the task of observing chromosome behavior because only the maize chromosome is visible. With the RH lines it will be possible to study the effect of removing specific chromosome regions. Specific chromosome landmarks (such as centromeres) can be isolated from other chromosome constituents in RH lines and observed. Second, flow cytometry can physically separate the maize chromosome from the oat chromosomes.[9] It will be possible to make chromosome-specific libraries or libraries enriched for specific chromosome regions. Third, expression of maize genes in a foreign environment can be investigated. Ectopic expression of the liguleless3 gene in chromosome 3 oat-maize chromosome addition lines produces a characteristic hooked panicle phenotype reminiscent of the liguleless3 mutant phenotype in maize.[10] Other phenotypes have been associated with particular chromosome addition lines.[11] Expression studies may determine the gene(s) responsible, and radiation hybrid lines may be an effective means to transfer traits from one species to another.

CONCLUSION

The set of oat-maize chromosome addition lines and RH lines is making important contributions to our knowledge of the physical organization of the maize genome. However, it is likely that BAC contig maps and genome sequencing will supplant RH maps and other physical maps of the maize genome for the purpose of mapping. RH mapping and other physical mapping techniques may remain useful in specific situations—for example, creating maps in species with very large genomes or where there is not the economic incentive to invest in contig maps and genome sequencing. The long-term value of RH mapping may therefore derive from other uses envisioned for the oat-maize radiation hybrid lines.

Recombination and Genetic Variation

Clifford F. Weil
Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

Homologous recombination contributes to genetic diversity by breaking associations between alleles of genes on the same chromosome. Recombination can also produce translocated or inverted chromosomes, alter gene number in repetitive families, and, in some cases, create entirely new genes by mixing parts of existing genes and creating short regions of heteroduplex that result in mutations. The majority of recombination in plants occur during meiosis, although mitotic crossovers and recombinations among extranuclear genomes are also observed. Because plants form gametophytes late in development, all three contribute to genetic diversity. This review touches briefly on reciprocal and nonreciprocal genetic exchanges in plants, both meiotic and mitotic. The reader is referred to a rich and growing literature in this field (hardly done justice here), with apologies to those whose work is not cited because of space constraints.

Recombination and its role in genetic diversity can be studied at the population level where, for example, recombination contributes to increasing variation in fitness of individuals and may be favored under selective pressure. However, increasingly, diversity is assessed at the molecular level, and patterns of nucleotide diversity are correlated with patterns of crossover events along chromosomes. Overall, regions with lower recombination tend to show less sequence divergence, although this is not always the case.

The mechanics of recombination also influences genetic diversity in plants. For example, recombination does not occur uniformly throughout the genome and, in some species, shows different frequencies in male and female meiosis; the reasons for these differences remain unknown. Cytological studies of recombination and meiosis in plants over more than a century laid extensive groundwork for more recent genetic and molecular studies in maize, tomatoes, rice, Arabidopsis, and wheat, to name only a few. Additional levels of both complexity and control are being recognized in the recombination mechanism as a result of these studies.

MEIOTIC RECOMBINATION

Physical exchange between homologous chromosomes is an important step early in the alignment of chromosomes prior to full synapsis and is important for efficiently dispersing chromosomes during meiosis I. Proteins such as plant homologues of Rad51 and Dmc1 are implicated in homology searching between sequences, although the precise mechanism in plants remains unclear. Detecting homology becomes even more exacting in plants, where allopolyploidy can be relatively common. There, recombination generally occurs between homologous pairs, rather than between homologs.

Chromosome structure also plays an important part in dictating where recombination events between homologues initiate and the diversity of particular regions of a genome. For example, chromosomal inversions suppress diversity because recombinant products are typically lost as acentrics or dicentrics. It is also likely that interphase chromatin structure plays a key role in dictating where recombination events initiate. Individual genes that may suppress meiotic recombination would be of tremendous value because loss-of-function mutations in them would likely increase recombination, which is of great potential use to breeders.

At the other end of the process, points where sequence homology between chromosomes begins to break down (e.g., ends of genes, or, in some cases, ends of exons) are often frequent positions at which branch migration is stopped and Holliday structure resolution takes place. These positions are where recombinant sequence joints are located. Therefore proteins that control where exchanges are resolved help determine the limits of where sequence diversity will occur because of recombination. The Mus81 protein has been implicated as the resolvase enzyme in fission yeast and animals, although not in budding yeast, and a plant homolog has not yet been characterized. Interestingly, overexpressing a bacterial Holliday junction resolvase (RuvC) in plants stimulates somatic recombination; however, there is no evidence yet to support an increase in meiotic recombination.
Although the position of recombination events is one side of the coin, recombination frequency is the other. The rate of meiotic recombination is very likely under multiple levels of genetic control in many plant species. Variations in rate have been reported among accessions of Arabidopsis and between inbred lines in maize. In addition, candidate genes for these modifiers are beginning to be identified (e.g., the maize desynaptic gene and the Arabidopsis SWI1 gene).

An important complex that may control both position and rate of meiotic recombination in plants can be seen in the electron microscope. Elliptical, proteinaceous ‘‘recombination nodules’’ associate with crossover events in the synaptonemal complexes of maize, tomatoes, and lilies. Similar nodules are observed in yeast and animal systems. The so-called ‘‘early nodules’’ convert into morphologically distinct ‘‘late nodules’’ that remain associated with chiasmata, and these late nodules cause the release of any other nearby early nodules. This relationship between nodules may explain ‘‘crossover interference’’—the inhibition of one crossover event on formation of others nearby. The content of recombination nodules remains unknown, but may include the MLH1 mismatch repair protein. It will be interesting to see whether Arabidopsis has recombination nodules and how they interact; Arabidopsis may have two different meiotic recombination pathways, only one of which is subject to crossover interference.

UNEQUAL CROSSING OVER AND ILLEGITIMATE RECOMBINATION

Families of repetitive genes can serve as reservoirs of diversity by providing functional redundancy in the genome. In cases of tandemly repeated genes (e.g., rDNA repeats), recombination using sequence homology between misaligned members of a gene family can alter the number of family members present on each of the two homologues.

An additional outcome can be switching or alteration of coding sequences among members of a gene family. Examples of this include the maize R1 locus and the Xa21 disease resistance genes of rice. Rearrangements at the R1 locus also result in novel, developmental patterns of gene expression as coding sequences and promoter of elements exchange.

On a larger scale, plants show an enormous diversity in overall genome size. Much of the variation is attributed to accumulation or removal of transposable elements. Illegitimate recombination is likely to be a means of limiting or even reducing the size of plant genomes.

NONRECIPROCAL EXCHANGE (GENE CONVERSION)

Exchange of information without the exchange of flanking markers occurs in plants. The alternative explanations for these exchanges are gene conversion or reciprocal, double crossover events. In organisms such as fungi, where all the products of a single meiosis can be accounted for, gene conversions are scored readily and conclusively as deviations from the typical Mendelian segregation of alleles. In plants, this has been more complicated, although the evidence, while indirect, is extremely compelling. For instance, double crossover events in some cases (e.g., maize) are deemed unlikely because crossover interference (see above) is extremely high. Taking a more theoretical approach, Haubold et al. used the relationship between physical distance and linkage disequilibrium along a 170-kb piece of the Arabidopsis genome to estimate as much as 90% of the observed recombination, which is, in fact, gene conversion. Whether this is the case for the rest of the genome or for other plants remains to be seen. The most promising development has been the quartet mutation in Arabidopsis, which causes all four pollen grains formed from a single meiosis to remain joined, effectively allowing fungal-style tetrad analysis and the possibility of formally demonstrating gene conversion. Data from yeast have shown that crossover and noncrossover products of recombination arise at different times during meiosis, and it will be interesting to see whether the same holds true in plants.

MITOTIC RECOMBINATION

Plants show low rates of somatic, homologous recombination, possibly because the highly repetitive nature of many plant genomes would make frequent illegitimate recombination a problem. An important consequence of this low rate has been a frustratingly low level of homologous gene targeting (with the curious exception of the moss Physcomitrella). Numerous, cleverly designed constructs have been used to enhance recovery of somatic homologous crossovers (e.g., Ref. [14]). These constructs have also helped identify cis-acting and trans-acting factors involved in mitotic recombination. Complementation of yeast mutations such as rad1, rad25, sgs1, and others using plant genes has been used to identify specific functions that might relate to mitotic recombination (e.g., helicase, exonuclease, or endonuclease activities), but whether the complementing plant genes are directly homologous is less clear. A curious result of these studies has been that mutations in DNA repair genes
such as Rad50 seem to cause mitotic hyperrecombination phenotypes, suggesting that the normal roles of these genes may include suppressing somatic recombination.[16]

CONCLUSION

Understanding the contributions of recombination to genetic diversity and how they occur remains an important research area for the future. Of the three primary engines of diversity (mutation and rearrangement being the other two), recombination serves as the most frequent, probably the most regulated, and arguably the most important.

INTRODUCTION

The expansion of agriculture is widely held to be one of the causes of tropical deforestation. Simply stated, the progressive expansion of agriculture into areas of tropical forest can only occur when forests are slashed. There is little doubt that in many places an increased need for agricultural land goes hand in hand with expansion into forestland. However, the relationship between agricultural expansion and tropical deforestation is more complex than a simple addition and subtraction formula suggests. Many forms of tropical agriculture are integrated with forestry activities. Forests play an important role in the complex of resource management among many farmers in the tropics. Although such tropical agroforestry is no alternative for strict forest conservation in protected areas, it is a viable alternative—especially from a conservation point of view—to other agricultural development schemes that are often proposed or blindly copied in many tropical countries.

SWIDDEN AGRICULTURE AND FOREST MANAGEMENT

One of the most common types of agriculture in areas of tropical rainforest remains swidden agriculture. Swidden agriculture implies using a single field for intensive cultivation for one or a few years, after which the field is fallowed. During the intensive production cycle farmers grow crops like rice, manioc, and bananas, usually in combination with a few or many other crops. The reason farmers practice swidden—rather than permanent—agriculture is that soils’ natural nutrient reserves do not permit permanent annual cropping. In most cases, the main purpose of the fallow period is to allow the restoration of the nutrient stock in the vegetation. This nutrient stock is released again into the soil when, at the end of the fallow period, the vegetation is slashed and burned. This new nutrient boost allows a subsequent round of intensive crop production. An additional benefit of the fallow vegetation is the reduction of obnoxious weeds that put high pressure on farmers’ labor reserves and may also reduce crop yields.

Forests do constitute an important role in many swidden fallow agricultural systems. They are where swidden fields are originally developed. The vegetation that grows on swidden fields that are being fallowed will eventually develop into secondary forests. Besides the nutrient restoration, these swidden fallow secondary forests are also important for forestry production. Forestry production is an important component of many swidden agricultural systems. This forestry production may occur in forest remnants that have been spared from conversion to agricultural lands. It may also occur in so-called secondary forest gardens—fields that were once used for agriculture, but that have changed to tree vegetation resulting from the partly spontaneous/partly actively pursued regrowth of trees.[1]

Forest Remnants and Primary Forest Gardens

In the remote corners of the world, where most swidden agriculturists reside, forests supply an important number of products for daily needs. They supply food, like edible leaves, mushrooms, berries, and game. In addition, they also supply construction material to build houses, medicinal plants, and sites where spirits are believed to reside and where graveyards are made. Considering this importance of forests, many swidden farmers may spare important areas of forests when advancing their agricultural fields into the forest. Examples of these forest remnants can be found in many locations. They are reported mostly in countries in Southeast Asia.[2,3] They are also common in many rural areas in Africa, where they are kept as sacred groves. These groves hold important spiritual meanings for the people who protect them.

Most primary forest gardens are safeguarded from conversion to agricultural land for the sake of assuring the supply of a wide range of forest products. Some forest gardens, however, are known for their production of economically important species. For instance, small producers cultivate Psychotria ipecacuanha, a medicinal
Swidden Fallow Secondary Forests

The most common type of forests co-occurring with swidden agriculture is the swidden fallow secondary forest. These forests regenerate largely through natural processes in woody fallows of swidden agriculture for the purpose of restoring the land for cultivation again. In a typical swidden fallow land use system, swidden fallow secondary forests often constitute the largest part of the area under some kind of vegetation cover. Besides their role in restoration of nutrient stocks, this type of forest is habitat for an important number of species that have some use value for their owners. Because these forests are usually located closer to settlements than are primary forests, they often may be the first place where farmers will turn to collect forest products.

Although swidden fallow secondary forests have often been classified as degraded forests, there is increasing evidence of their importance in fulfilling the functions that primary forests used to fulfill: conservation of biodiversity, regulation of the water flow that affects downstream areas, and carbon sequestration. It can indeed be expected that in many places of the world these functions will increasingly be fulfilled by some kind of secondary forest.

Secondary Forest Gardens

Secondary forest gardens are managed forests that appear on land once used for cropping that has subsequently been designated for forestry production. In addition to spontaneous vegetation, these forest gardens hold a number of species that may be planted or tended after they occur spontaneously. They play an important role in the livelihood of many farmers, precisely because they provide a larger suite of products than natural forests or primary forest gardens. They may occupy significant areas in swidden agricultural villages all over the world.

---

Chokkalingam and de Jong [1] distinguish six types of secondary forests, two of which are related to swidden agriculture: swidden fallow secondary forests and secondary forest gardens.

---

CONCLUSION

Although a diverse swidden agriculture landscape with its mixture of anthropogenic forests may not be a better alternative to true conservation in protected areas, such
a landscape suggests an important potential in other instances. The kind of agriculture–forestry interaction described here has many conservation and environmental advantages over other large-scale estate plantations and other kinds of intensified agricultural production such as oil palm production, pulp-wood plantations, and the like. Where it is necessary to make alternative choices, it is useful to consider the benefits that intensified swidden agriculture production may offer, including intensified forestry production as described here. Second, where efforts at development of swidden agriculture are pursued, it matters to an important degree to what extent traditionally managed forests are being taken into consideration. This will have different impacts on the forest, the biodiversity in the landscape, and the watershed protection that this landscape provides.

Regeneration from Guard Cells of Crop and Other Plant Species

Jim M. Dunwell
University of Reading, Reading, U.K.

INTRODUCTION

Guard cells, the components of the stomata within the leaf epidermis, are usually considered to be terminally differentiated and only of interest to plant physiologists concerned with gas exchange within the leaf. However, as will be described, these cells are of much greater general interest for their capability of being induced into division and even regeneration into complete plants.

HISTORY

Examination of the botanical literature from the last hundred years reveals several reports of abnormal development of guard cells from a variety of species. These references have been largely overlooked and only relatively recently[1] has there been any real discussion of their significance. Among the early studies was the first attempt to induce division in mature guard cells in vitro.[2] It was more than sixty years before this specific ambition was achieved, although during that period, evidence of guard cell division was reported in wounded leaves of various magnoliaceous species[3] and in cucumber (Cucumis sativus) hypocotyls exposed to particular red light conditions.[4]

DIVISION AND REGENERATION IN VITRO

There are three examples in which complete plants have been produced from guard cells in vitro; these will be considered in sequence below.

Tree Tobacco (Nicotiana glauca)

The first report of successful cell division in vitro involved an accidental discovery with cultured guard cell protoplasts of N. glauca. These were being grown in culture in an attempt to mimic normal development, but surprisingly some were found to develop into undifferentiated callus. Subsequently, experiments were performed to optimize conditions for culturing such protoplasts and to determine whether they were indeed totipotent.[5] Protoplasts were isolated from adaxial epidermal tissue of leaves of plants grown under fluorescent light (800–900 μmol m⁻² s⁻¹ of photons of photosynthetically active radiation [PAR]). To increase the probability that the guard cells were of uniform osmotic potential at the time of harvest, leaves were collected in darkness, just before the beginning of each light period. Protoplasts were cultured in liquid media similar to those used for culturing mesophyll cell protoplasts of Nicotiana tabacum but with modified pH and KCl, CaCl₂, sucrose, and glycine concentrations; concentrations of growth regulators were 0.3 mg 1⁻¹ α-naphthaleneacetic acid (NAA) and 0.075 mg 1⁻¹ of 6-benzylaminopurine (BAP). Protoplasts were incubated in darkness at 25°C in 8-well microchamber slides at a density of 1.25 × 10⁵ cells ml⁻¹. Cell divisions began within 72–96 hours (h) of initiation of cultures, with an average cell survival of 57% at this time. After 8–10 weeks of culture, cell colonies were transferred to a callus initiation medium containing agar and incubated under continuous white fluorescent light (25 μmol m⁻² s⁻¹ of photons of PAR) for another 8–10 weeks. Green callus tissue was then transferred to a callus growth medium and incubated under the same conditions. After a further 8–10 weeks, the callus was transferred to a shoot differentiation medium and incubated similarly. Two weeks later multiple shoots appeared and were transferred to a root differentiation medium. When roots were sufficiently developed (6–8 weeks), plants were transplanted to soil and grown in a growth chamber. It was concluded that guard cell protoplasts could survive and divide in culture and are totipotent.

In a later study,[6] additional modifications in protocol were reported that allowed directed development either to callus production or to maintain normal guard cell behavior. In particular, it was shown that temperature is an important determinant of survival, growth, and differentiation. As the temperature was increased from 24 to 32°C, the survival of cells cultured for 7 days (d) was increased from approximately 20% to approximately 80%. At all these temperatures, approximately 90% of surviving cells divided to form callus tissue. Cells cultured for 7 d at 34 to 40°C also survived in high percentages (approximately 80%), but in contrast, they retained a morphology similar...
to that of guard cells and they did not divide. These observations were explored further in a later study using differential display technology to define the various cell types.\[7\]

**Sugar Beet (Beta vulgaris)**

The most valuable practical application of guard cell culture is that developed for sugar beet. This procedure was founded initially on the application of advanced microscopical techniques to address a difficult culture problem.\[8\] Using a computer-controlled microscope system to assist in the positioning and rapid relocation of large numbers of cultured cells, it was found to be possible to identify those specific leaf protoplasts with the capacity to divide within a highly recalcitrant culture in which only a tiny fraction (0.5%) of the total population was able to produce viable microcalli. It was discovered that such regenerable microcalli come only from guard cell protoplasts (60% capacity for cell division), and not from protoplasts derived from mesophyll or other leaf tissue. This important discovery led to the development of an optimized protocol for the efficient and rapid genetic modification of this species.\[9,10\] This involved a polyethylene glycol-mediated DNA transformation technique applied to protoplast populations enriched specifically for this single totipotent cell type in order to achieve high transformation frequencies. Bialaphos resistance, conferred by the *pat* gene, produced a highly efficient selection system. The majority of plants were obtained within 8 to 9 weeks of selection and were appropriate for plant breeding purposes; all were resistant to glufosinate-ammonium–based herbicides. Detailed genomic characterization revealed verified transgene integration, and progeny analysis showed Mendelian inheritance. This system has since been applied to the large-scale production of a range of transgenic sugar beet.

**Cotton (Gossypium hirsutum)**

The most recent extension of this technology is its application to cotton,\[11\] a species generally considered recalcitrant to many regeneration methods. Rather than relying on protoplast isolation, this method comprised development of a regeneration system from stomatal guard cells directly on epidermal strips, especially from bracts. The most important factors affecting embryogenic callus initiation in both of the varieties tested (Coker 312 and 315) were the source of the epidermal tissue, including plant age (4–5 months old), the developmental stage of the flower (opening flower stage) from which bracts were obtained, the composition of the culture medium, and light irradiance. The flower developmental stage was critical for callus formation, which was observed only from bracts obtained from opening flowers. In addition, epidermal strips excised from the bract basal region were more responsive in culture than those obtained from the upper region. Improved callus initiation was obtained on epidermal strips, which had their cuticle in contact with the culture medium. Light irradiance was a limiting factor for embryogenic callus formation, which was observed only in calli cultured under the lower light irradiance (15.8 \( \mu \text{mol m}^{-2} \text{s}^{-1} \)). Somatic embryogenesis was observed on callus cultures subcultured consecutively in a culture medium containing NAA (10.7 \( \mu \text{M} \)) and isopentenyladenine (4.9 \( \mu \text{M} \)). Histodifferentiation of somatic embryos was improved in a medium containing NAA (8.1 \( \mu \text{M} \)), isopentenyladenine (2.5 \( \mu \text{M} \)), and abscisic acid (0.19–0.38 \( \mu \text{M} \)). Somatic embryo germination and plantlet development were obtained using established protocols with few modifications, and on average, one fully developed plant was obtained from the culture of about 100 epidermal strips in both cultivars.

**CONCLUSION**

It is likely that future investigations will extend the number of species from which totipotent guard cells can be isolated, either in intact epidermis or as protoplasts.\[1,12\] In many ways the development of this procedure has mirrored the development of regeneration methods for another unusual and isolated cell type—namely microspores—that were also once considered to be a developmental dead end but were then shown to have a high level of totipotency.

It can also be assumed that methods for the isolation of RNA from guard cells\[13\] will be applied to this particular culture process in order to investigate the details of this profound switch from the normal differentiated state to one capable of division.

Apart from the value of guard cells as a source of totipotent material for use in transformation experiments (e.g., sugar beet) and perhaps the regeneration of other transgenic plants in the future,\[1,12\] stomatal formation in *Arabidopsis thaliana* is also emerging as an elegant and powerful model system to study the genetic and molecular control of cell-fate specification and pattern formation in multicellular organisms.\[14\] Eventually it is hoped that the combination of these emerging analytical methods will help to not only uncover the nature of the molecular signals that restrict the developmental potential of guard cells in situ, but also allow more predictable methods for the induction of division in such cells when they are separated from the plant.

Retrotransposons and Their Contributions to Plant Genome and Gene Evolution

Amar Kumar
Scottish Crop Research Institute, Invergowrie, Dundee, U.K.

INTRODUCTION

Transposons are mobile genetic elements that have capacity to move from one to another location within host chromosomes. Retrotransposons are class I transposable elements, transposing via an RNA intermediate that is reverse-transcribed into extrachromosomal DNA and inserted into the genome by the encoded reverse transcriptase, RNaseH, and integrase enzymes. This replicative mode of transposition is similar to animal retroviruses. However, unlike the retroviruses, which are found only in animals, retrotransposons are found in all eukaryotes, where they are the most abundant class of mobile DNA. Moreover, retrotransposons constitute a major portion of all eukaryotic nuclear genomes and are commonly found as repetitive sequences interspersed on the entire length of host chromosomes. Many properties of transposable elements suggest that they are parasitic or selfish DNAs. However, as in any other component of a heritable genome, transposon DNA can serve as a genomic resource for mutation and natural selection. Indeed, a more recent paradigm suggests that transposable elements may play a central role in the evolution of gene function and genome structure in eukaryotic organisms. For example, transposons can contribute regulatory cis-factors, alter transcript splicing, promote exon shuffling, and facilitate chromosomal rearrangements or restructuring leading to changes in spatial and temporal expression patterns of host genes or even generation of novel genes. Furthermore, retrotransposons are involved in altering the genome size of eukaryotic organisms either by increasing or by decreasing their copy numbers within the host genome.

STRUCTURE, ABUNDANCE, AND DISTRIBUTION OF RETROTRANSPOSONS

Retrotransposons are classified into two types: those with long terminal repeats (LTRs) and those without LTR (non-LTR retrotransposons). Long-terminal-repeat retrotransposons are further subclassified into the Ty1-copia and the Ty3-gypsy groups that differ from each other in both their degree of sequence similarity and the order of encoded gene products (Fig. 1). Ty1-copia retrotransposons are present throughout the plant kingdom, in species ranging from single-cell algae to bryophytes, gymnosperms, and angiosperms. Ty3-gypsy retrotransposons are also found widely distributed in the plant kingdom, including both gymnosperms and angiosperms. Furthermore, both these groups of retrotransposons are commonly found in high copy number (up to a few million copies per haploid nucleus) in plants with large genomes (Table 1). Nonautonomous LTR retrotransposons (i.e., lacking mobility-related proteins) are also abundant in plant genomes, and recently, a new group of such elements has been identified that are ubiquitous in plants. The non-LTR retrotransposons, long interspersed repetitive elements (LINEs) and short interspersed repetitive elements (SINEs), have also been found in high copy numbers (up to 250,000) in plant species studied to date. Like the LTR retrotransposons, both LINEs and SINEs are present throughout the plant kingdom. All in all, plant genomes, such as higher eukaryotic genomes, contain an exceptionally abundant and diverse set of retrotransposons: by contrast, functional retroviruses are either absent or present in very small numbers in the plant genomes. Table 1 shows a list of some well-characterized retrotransposons in plants.

REGULATION OF EXPRESSION AND TRANPOSITION

The expression of retrotransposons in plants and in other eukaryotic organisms is regulated, thereby regulating their transposition frequency in the host genome. The evolution of control mechanisms for the transcription and transposition of retrotransposons in the host genome may be crucial to minimize their possible deleterious effects on the host. A correlation between transcription and transposition of retrotransposons has
been demonstrated for the tobacco Tto1 and rice Tos17 retrotransposons. For example, transposition of Tto1 and Tos17 was concomitant with an increase in the levels of their RNAs, suggesting that transposition of these retrotransposons is regulated mainly at the transcriptional level. Many of the plant retrotransposons (e.g., Tnt1 and Tto1) studied to date are transcriptionally activated by various biotic (e.g., inoculation with various viral, bacterial, or fungal pathogens) and abiotic (e.g., cell culture, wounding, methyl jasmonate, CuCl2, and salicylic acid) stress factors.

CONTRIBUTIONS OF RETROTRANSPOSONS TO THE EVOLUTION OF PLANT GENES AND GENOMES

Gene Mutation

Retrotransposons are involved in generating mutations through insertions near or within genes. Both LTR and non-LTR retrotransposons have generated mutations in plants. For example, a retrotransposon-induced mutation was responsible for the generation of white color skin in...

grape cultivars. Many retrotransposon insertions within or close to genes affect their expression in a negative fashion by decreasing or abolishing transcription of the gene or by detrimental alterations in transcript processing and/or stability. In other cases, however, insertion of retrotransposon sequences within or near a gene has more complex effects on gene expression, including alterations of temporal and spatial patterns of transcription or the structure of the resultant protein. Interestingly, many plant genes currently considered wild type contain legacies of previous retrotransposon insertion.

**Genome Size**

Retrotransposons play a major role in determining the size of plant genomes. For example, small genomes in plants such as *Arabidopsis* (1C equal to about 130 Mbp), which only contains about 10% of the total genome as retrotransposons, might be the consequence of a lack of retrotransposon proliferation or/and a gradual elimination of retrotransposons. On the other hand, large genomes in plants such as maize (1C equal to about 3200 Mbp) might be the result of successful colonization and amplification of retrotransposons. An estimated divergence time between maize and sorghum is about 15–20 million years ago, and both have 10 chromosome pairs, but the maize nuclear genome is 3–4 times longer than the sorghum genome. Molecular hybridization and sequence analysis data have revealed that the increase in maize genome size was largely caused by an extensive proliferation of retrotransposons that has occurred within the last 2–6 million years. Nonetheless, retrotransposons are also responsible for the reduction of plant genome sizes following gradual elimination of their sequences, by various mechanisms, such as unequal recombination between the LTRs of an LTR retrotransposon (to generate solo LTRs) or other types of deletion. Interestingly, a correlation was shown between the *BARE-1* retrotransposon copy number and genome size in wild barley and the sharply differing microclimates in Evolution Canyon near Mount Carmel, Israel. This suggests the dynamic nature of the barley genome with respect to retrotransposon activation by environmental stimuli.

**MOLECULAR TOOLS FOR PLANT GENOME ANALYSIS**

**Molecular Markers for Phylogenetic, Biodiversity, and Genetic Linkage Analyses**

There are several advantages in using retrotransposon sequences as molecular markers. They are ubiquitous, present in high copy numbers as highly heterogeneous populations, are widely dispersed on chromosomes, and show insertional polymorphism both within and between species in plants. Furthermore, active retrotransposons will produce new insertions in the genome, leading to polymorphism. The new insertions may then be detected and used to temporally order insertion events in a lineage, helping to establish phylogenies. These genetic properties have recently allowed retrotransposons to be exploited as DNA markers to study biodiversity in maize, pea, and barley and to generate genetic linkage maps in barley and pea.

**Gene Tagging and Functional Analysis of Genes**

Some retrotransposons have features that make them ideal genetic tools for gene tagging in plants. These include 1) retrotransposon-mediated insertion mutations that are stable because they transpose by a replicative mode, 2) transposition target sites that are unlinked to the site of the original copy, making it relatively easy to generate a large collection of random insertions for saturation mutagenesis, 3) transposition that can be regulated by abiotic and biotic stress conditions, 4) high mutagenicity as a result of preferential transposition into genes. In rice, the endogenous *Tos17* retrotransposon meets all the conditions mentioned above for its use in tagging genes. *Tos17* is highly active under tissue culture conditions and preferentially inserts into or near genes. It has been used to generate a large collection of random insertions for saturation mutagenesis and has been used to clone a number of genes in rice.

**CONCLUSION**

We now know that plant retrotransposons are responsible not only for generating mutations in plant genomes, but also for significantly increasing the size of many plant genomes. Their replicative modes of transposition have equipped them with the ability to proliferate rapidly within their hosts, allowing them to become a major component of higher plant genomes. Retrotransposons are also one of the most fluid of genomic components, varying greatly in copy number, genomic localization, and sequence structure over relatively short evolutionary times. These properties make retrotransposons one of the major forces influencing the structure of plant genomes. Although their initial and major continuing motivation appears to be selfish and/or parasitic, retrotransposons will continue to be used whenever possible by their hosts. Finally, it is clear from the above and other published reports that retrotransposons are central players...
Retrotransposons and Their Contributions to Plant Genome and Gene Evolution

in the structure, evolution, and function of plant genomes. Hence retrotransposons may be selfish but are certainly not junk. In fact, they are not even very selfish because both host genome and scientists can use them for their own benefit.

Rhizodeposition: Composition and Quantitative Aspects

Günter Neumann
Institut für Pflanzenernährung, Universität Hohenheim, Stuttgart, Germany

INTRODUCTION

Carbohydrate partitioning from shoot to roots can comprise a substantial proportion of plant-photosynthetic CO₂ fixation (20–70%), and out of this fraction 4–70% can be released into the soil as organic rhizodeposition.[1,2] This is not only a significant loss of reduced carbon but can also contribute by 30–40% to the total input of soil-organic matter[2] with considerable impact as a source of carbon and nitrogen for soil microorganisms. Rhizodeposition is associated with dramatic changes in the activity and composition of soil-microbial communities, solubility of nutrients and toxic elements in the root environment, determining the rhizosphere as a compartment with major influence on pools, and fluxes of carbon and mineral nutrients in soils.

According to the mechanisms of release, organic rhizodepositions may be grouped into two major fractions: lysates, leachates from sloughed-off cells, and dead tissues as a consequence of root turnover. In contrast, root exudates (2–10% of translocated carbon) are released from intact root cells either passively as diffusates or actively as excretions or secretions with specific functions.[2,3] Rhizodeposition can be enhanced in response to high light intensities, temperature extremes, the mechanical impedance of the substrate, toxic elements, low soil pH, nutrient limitation, and presence of microorganisms. It is affected by the plant-developmental stage and by expression of retrieval mechanisms in plant roots, which are able to recover up to 90% of amino acids and sugars released into the rhizosphere.[3]

SLOUGHED-OFF CELLS AND TISSUES

Organic compounds released from sloughed-off root cells and tissues are a major carbon source for rhizosphere microorganisms but may indirectly have an impact as microbial metabolites on nutrient availability and on exclusion of toxic elements in the rhizosphere.[4] However, even the liberation of sloughed-off root cells (root border cells) is a controlled process, which exhibits genotypic differences between plant species and can be modified by various environmental factors. Border cells are able to produce antibiotics and attract root pathogens, thereby counteracting infection of the apical meristem. In response to infection with pathogens and to toxic aluminum levels, root border cells exhibit enhanced mucilage secretion, which seems to repel bacteria and alleviates aluminum toxicity.[5] Limited longevity is also characteristic for root hairs and fine roots. Continuous root turnover is a general feature of plant development and insoluble root debris may comprise 50–90% of total rhizodeposition.[6]

HIGH MOLECULAR WEIGHT COMPOUNDS

High molecular weight compounds, such as mucilage and ectoenzymes, are actively released via exocytosis. Mucilage is released from hypersecretory cells at the root cap as a gelatinous polyuronic acid polysaccharide. Subsequently, the secretory cells degenerate or are sloughed-off as root border cells. Mucilage has protective functions for the root meristem and improves root–soil contact by inclusion and aggregation of soil particles. A function as lubricant seems to be unlikely, since no water retention or swelling capacity can be demonstrated at water potentials <0. Mucilage secretion can facilitate Zn²⁺ transport from embedded soil particles to the root surface. It may also contribute to P desorption and to exclusion of toxic elements (Al, Cd, Pb) by complexation with galacturonates mainly in exchange with Ca²⁺.[7]

Under P deficiency, enhanced root-secretion of phosphohydrolases (e.g., acid phosphatases, nuclease, phytases) can increase P availability by hydrolysis of organic P esters, comprising 20–80% of the total soil phosphorus (Fig. 2). Considerable genotypic variation exists in the ability of plant species for secretion of phosphohydrolases. In many soils, however, enzymatic hydrolysis is limited by low solubility of organic P forms (Ca/Mg and Fe/Al phytates). Another limiting factor is also the low solubility of secretory phosphohydrolases, restricted by immobilization at the cell wall or by adsorption and inactivation on clay minerals. Root-secretory phosphohydrolases may also contribute to P retrieval by hydrolysis of organic P, permanently lost into the rhizosphere from damaged root cells.[7,8]
LOW MOLECULAR WEIGHT COMPOUNDS

A wide range of low molecular weight compounds (e.g., sugars, amino acids, carboxylates, phytosiderophores, phenolics, vitamins, hormones) are released from plant roots. Particularly, certain phenolics, carboxylates, and phytosiderophores, which exhibit reducing properties and the ability for metal complexation, can directly affect the availability of nutrients and of toxic elements in the rhizosphere. A significant utilization of chelated metals by plant roots usually requires complex splitting by root-induced pH changes or metal reduction (Fe, Mn, Cu) at the root surface or in the apoplast.

Metal complexation by carboxylates is, on the other hand, an important mechanism to exclude uptake of toxic elements, such as Al$^{3+}$ in plant species and cultivars adapted to acid mineral soils (Fig. 1). Exudation of Al-chelating carboxylates (malate, citrate, oxalate) is triggered within minutes to several hours after exposure to Al$^{3+}$. The release is restricted to the apical root zones, which are most susceptible to toxic effects of aluminum.$^{[3,9]}$

Phosphorus deficiency-induced root exudation of carboxylates and H$^+$ can mediate the mobilization of sparingly soluble Ca phosphates in calcareous soils and of Fe/Al phosphates in acidic soils by mechanisms of ligand exchange, dissolution, and occupation of P sorption sites (Fig. 2). Among the various carboxylates in plant root exudates, citrate and oxalate are most efficient in P mobilization but significant P desorption
usually requires high carboxylate concentrations (>1 mM) in the equilibrium solution. Comparable rhizosphere concentrations have so far been reported only for a limited number of plant species such as Lupinus albus, Trifolium pratense, and members of the Proteaceae. Under P deficiency, root exudation of carboxylates is frequently preceded by organic acid accumulation in the root tissue, which has been related not only to increased biosynthesis but also to reduced turnover of organic acids.[3]

In graminaceous plants, release of nonproteinaceous amino acids (mugineic acids)—so-called phytosiderophores (PS)—with a high capacity to form stable chelates with Fe\(^{3+}\) even at high soil pH > 7, is a strategy to cope with low Fe availability in alkaline soils. Subsequent root uptake of Fe\(^{3+}\)-PS complexes is mediated by a specific transport system (Fig. 3). Phytosiderophores can also mediate the extraction of considerable amounts of Zn, Mn, Cu, and even Cd and Ni in calcareous soils. Tolerance of graminaceous plants to Fe and Zn deficiency is roughly related to the amount of PS released in response to Fe and Zn starvation. However, considerable genotypical variation exits within each single plant species. Biosynthesis of PS increases in the root tissue under limited Fe supply even before Fe chlorosis appears, and rapidly declines after resupply of iron. Phytosiderophores are derived from nicotianamine as a trimerization product of \(S\)-adenosyl methionine with subsequent transamination and hydroxylation.[3]

Localized release of root exudates in apical root zones with a low density of microbial colonization and secretion peaks over a limited period of time may counteract rapid microbial degradation and thereby increase the rhizosphere concentrations of exudate compounds for mobilization of nutrients. In principle, root exudation of carboxylates and other low molecular weight compounds can be mediated by diffusion along the steep concentration gradient of organic solutes between the cytosol (millimolar range) and the rhizosphere soil solution (micromolar range). However, the selective secretion of chelating compounds involved in nutrient mobilization or exclusion of toxic elements may be mediated by specific transport mechanisms such as anion channels with a concomitant release of protons or K\(^+\) to maintain charge balance.[3,9]

In contrast to carboxylates, direct interactions of sugars and amino acids with soil minerals are weakly expressed due to the lack of charges or slow reaction kinetics with metal ions but may indirectly influence nutrient availability as products of microbial metabolism.[4,10]

Root-secretory phenolics have important functions as chemoattractants, as nod-gene inducers for rhizobia, as signaling compounds for establishment of mycorrhizal associations, and are also involved in pathogen and allelopathic interactions.[2,11,12]

**FUTURE PROSPECTS**

There is an obvious lack of noninvasive techniques for measurements of root exudation with a high spatial resolution and tracing origin and fate of organic compounds in the rhizosphere. Further miniaturization of sampling and analytical techniques (e.g., microprobes, reporter bacteria, isotopic tracer techniques, microsuction cups, capillary electrophoresis, image analysis) should facilitate nondestructive measurements of rhizosphere processes at a high scale of resolution.

Much more experience is required concerning effects of root exudates and rhizosphere products on mobility and plant availability of nutrients and toxic compounds in soils under different environmental conditions and at realistic rhizosphere concentration levels, considering also synergistic effects of simultaneous chemical reactions. Fertilization management,
breeding, or biotechnological approaches may be employed for manipulation of the rhizosphere toward improved plant efficiency for nutrient acquisition, resistance to adverse soil-chemical conditions, or plant design for phytoremediation and phytomining strategies. However, first approaches to manipulate root exudation by simple overexpression strategies in transgenic plants revealed contradictory results,\cite{Delhaize2001} emphasizing the need for a detailed understanding of the physiological mechanisms involved in the regulation of root activity and of the related rhizosphere processes as well.

Rhizosphere Management: Microbial Manipulation for Biocontrol

Ben J. J. Lugtenberg
Faina D. Kamilova
Leiden University, Institute of Biology, Leiden, The Netherlands

INTRODUCTION

Several microorganisms—such as viruses, bacteria, and fungi—cause diseases on various plants, including economically important ones. Strategies to bring the disease level to economically acceptable levels include the use of chemical pesticides, plant cultivars resistant to a certain pathogen, and natural enemies. In the United States alone, over $600 million is spent annually on agricultural fungicides. The use of chemicals is increasingly discouraged because some are a threat to the environment and human beings. Nongenetically engineered disease-resistant plants are widely used. Drawbacks are that resistance is usually accompanied by a yield decrease (of approximately 3%) and that after a few years, forms of the pathogen take over to which the resistant plant is sensitive. A modern approach—the use of genetically engineered resistant plants—is not accepted in some economically important regions in the world, especially in Europe.

Biological control of plant diseases is becoming increasingly popular, wherein cultivated natural enemies of the pathogenic microbes are applied to seeds, seedlings, or plants in a concentration sufficiently high to compete successfully with the pathogen for several months.

BIOCONTROL AGENTS (BCAs)

Biocontrol agents represent all organisms, (including microbes, nematodes, and insects) that are able to decrease disease levels of crop plants. These diseases can be caused by pathogenic microbes, weed plants, or animals such as nematodes and insects. This article focuses on the biocontrol of plant diseases caused by soilborne pathogens. This control takes place in the rhizosphere (i.e., the root and its immediate surrounding area). The rhizosphere is relatively rich in nutrients and therefore attracts many microbes—pathogens as well as beneficials. Certain insects feed on plants to the extent that plants become seriously diseased or even die. Bacillus thuringiensis is a gram-positive soil bacterium able to produce crystalline inclusions during sporulation. These consist of proteins with highly specific insecticidal activity. They can be active against larvae of Lepidoptera, dipteran and coleopteran species. The crystals dissolve in the larval midgut where they are processed into smaller toxic proteins that generate pores in the midgut cell membrane. The larva stops feeding and consequently dies. Economically this is the most important application of biocontrol.

Many other plant diseases are caused by fungi, such as Alternaria, Botrytis, Fusarium, Gaeumannomyces graminis var. tritici, Pythium, Rhizoctonia, and Verticillium. Some pathovars of bacteria such as Agrobacterium, Erwinia, and Pseudomonas can cause crop damage also.

The BCAs used most frequently to control root diseases caused by fungi include the bacteria Bacillus, Pseudomonas, and Streptomyces, and the fungi Gliocladium and Trichoderma (Table 1). For more information, consult www.nal.usda.gov; www.epa.gov; www.bisolbi.com and www.biconet.com.

PROS AND CONS OF BIOLOGICAL CONTROL

In contrast to various chemical fungicides, BCAs are environmentally friendly. In cases, when they act through the production of an antifungal metabolite (AFM), this molecule is produced locally on the plant surface in small amounts. The molecule is biodegradable, does not reach drinking water, and is not harmful for workers.

In comparison with resistant plants, the use of BCAs has the advantages that: 1) they are inexpensive; 2) the decision to use them can be made relatively late; and 3) they do not cause a yield decrease, but have resulted in unexpected yield increases. Finally: 4) plants resistant to all pathogens do not exist; and 5) public perception of biologicals is positive.

Disadvantages also exist: 1) performance is not always consistent; 2) in comparison with chemicals, the shelf life of biologicals is short; 3) adoption of legislation governing the use of biologicals is an extremely slow process; and 4) the cost of registration is high, taking into account the small market share that biologicals currently represent.
ISOLATION OF BCAs

To test microbes for their action as BCAs, a system must be developed in which the plant is grown in the presence of the target pathogen. The disease pressure initially used is unnaturally high (60–80% diseased plants) in order to limit the number of plants required to produce a statistically significant result. Later, when the number of candidate BCAs is limited, larger experiments are carried out with lower disease pressure (20–40%).

Because biocontrol experiments are labor-intensive and time-consuming, scientists often make a prescreening or preselection, taking advantage of knowledge of mechanisms. For example, one can prescreen for organisms that inhibit growth of the pathogen (the antagonists) in vitro[2] or one can preselect enhanced colonizers.[3] This approach is biased by limited knowledge of BCAs’ mechanisms of action.

APPLICATION OF BCAs

After growth, biocontrol microbes usually are not applied immediately on the plant but are stored. To avoid major losses of viable organisms, they are treated by special methods (often protected by patents) that increase their survival during storage (their shelf life). This process is referred to as formulation. Survival is relatively easy when dealing with dormant forms called spores. When non-sporereformers are to be formulated, successful formulation is much more difficult, although major progress has recently been made. BCAs can be formulated in solid or liquid state and in materials such as alginate, bentonite, carragheenans, peat, or vermiculate. Alternatively, liquid seed-applied inoculants can be used. Ideally formulated, microbes can be used for more than one growth season so that leftovers from one season can be used at the beginning of the next. Formulated BCAs usually contain at least 10^9 viable microbes per gram or ml.[4] One of the most successfully applied microbes is *Bradyrhizobium japonicum*, a biofertilizer of soybean.[5]

Microbes can be applied on the seed or in the furrow before planting. Alternatively, they can be added to the plant during growth. BCAs are also used postharvest; for example, to protect oranges or potatoes from rotting during storage.

To monitor the success of BCAs’ application, it is important to monitor plant performance as well. In case of poor performance, data on the viability and activity of the BCA are crucial for understanding whether poor performance is due to the BCA or to other circumstances. Early discovery of the cause of poor performance should allow additional control measures. Because any individual form of disease control can fail, it is advisable to have a combination of methods available.

MECHANISMS USED BY BCAs

Important techniques to study mechanisms of biocontrol are visualization of differentially labeled pathogens (Fig. 1A) and BCAs (Fig. 1B), genetics, and biochemistry. The best studied form of biocontrol is the use of antagonistic microbes. These organisms produce one or more molecules (e.g., AFMs) that inhibit growth of the target pathogen.[6] To protect the whole root system against soilborne pathogens it is important that the BCA deliver the AMF along the whole root system.[7]

be done by applying a successful root-colonizing BCA on the seed, which subsequently colonizes the whole growing root. The production of AFMs often requires high cell densities of the BCA.\(^7\) Indeed, bacterial BCAs are often present as microcolonies (Fig. 1B). AFMs are diverse in structure. AFMs produced by several BCAs are 2,4 diacetyl phloroglucinol, phenazine, HCN, and biosurfactants.\(^6\) The latter molecules are thought to be particularly active against zoospores (e.g., from the pathogen *Pythium*).\(^8\)

Some BCAs act through parasitism or predation. For example, because many fungi contain chitin in their cell
walls, the secretion of chitinase is considered a trait of some BCAs (e.g., of *Trichoderma*).

Other BCAs colonize the root system very well but fail to produce AFMs or exoenzymes in vitro. Although one cannot exclude that some of these BCAs do produce AFM in the rhizosphere, it is often thought that this class of BCAs acts through competition with the pathogen for niches on the root or for nutrients secreted by the root. These so-called exudates often contain amino acids, sugars, and organic acids, albeit in low concentrations. 

BCAs of another class do not produce extracellular toxins, but induce a systemic reaction in the plant (e.g., the presence of certain *Pseudomonas* strains on the root triggers in the plant a faster, more severe response to pathogens present on the leaf). A variety of products of the BCA, including lipopolysaccharide, siderophores, and flagella, have been claimed to be involved in the induction of this form of resistance. It is assumed that bacteria that act through this mechanism, designated Induced Systemic Resistance,\(^9,10\) consist of subclasses that act by different mechanisms.

Using microbes labeled with autofluorescent proteins, confocal laser scanning microscopy studies showed that during biocontrol, hyphae of *Fusarium* become colonized by *Pseudomonas* BCAs (Fig. 1C). The resulting disabling of the pathogen may represent a novel biocontrol mechanism.

**CONCLUSION**

Mechanisms that allow for the isolation and construction of more robust strains are being developed. Clearly, the reduction of plant diseases by microbial control agents has a bright future.

Rhizosphere: An Overview

Roberto Pinton
Università di Udine, Udine, Italy

INTRODUCTION

Plant survival and adaptation to adverse soil conditions are strictly dependent on the capability of roots to interact with biotic and abiotic components of soil. Processes at the basis of the root-soil interaction concern a very limited area surrounding the root tissue. In this particular environment, exchanges of energy, nutrients, and molecular signals take place, rendering the chemistry and biology of this environment different from the bulk soil. In this chapter, an overview of the key processes occurring at the rhizosphere, which can account for the complexity of this environment, will be presented.

COMPLEXITY, DEFINITIONS, AND BOUNDARIES

The rhizosphere is a complex environment where almost every process involves multiple interactions between the soil-root-microbe triumvirate. It is well known that movement of water, nutrients, and microbial dynamics are more convoluted around the roots than in the bulk soil. Changes in pH and redox potential often occur. Furthermore, the rhizosphere generally experiences higher mineral weathering rates than bulk soil and is characterized by variable rates of mineralization of the native organic matter.

The term rhizosphere is generally used to define the field of action or influence of a root. Roots vary enormously in their morphology, longevity, activity, and influence on soil as a result of physiological, environmental, and genetic differences. It can be assumed that the rhizosphere forms around each root as it grows because each root changes the chemical, physical, and biological properties of the soil in its immediate vicinity.

The rhizosphere lacks physically precise delimitation; rather it can be described in terms of the longitudinal and radial gradients that develop along the axis of each root as a result of root growth and metabolism, nutrient and water uptake, rhizodeposition, and subsequent microbial growth. These will be gradients with depletion profiles (i.e., the solute concentrations will be lowest at the root surface), as in the case of the soluble organic solutes released by the roots.

The volume of the rhizosphere also depends on the rate of exudation and impact utilization of the rhizodeposits by microorganisms. Rhizodeposition includes lysates liberated by autolysis of sloughed cells and tissues, as well as biochemically defined root exudates released passively (diffusates) or actively (secretions) from intact cells. Exudation is not uniformly distributed along the whole root system. Usually apical root zones are characterized by a higher capacity for release of low-molecular-weight exudates, whereas basal parts of the root system generally show a higher microbial activity. This might affect rhizosphere microbial population. The longitudinal gradient of exudation may reflect the gradient in microbial catabolism of root exudates as well as differences in root cell activity. The gradients of microbial population and exudates along the root axis can have important implications for the uptake of nutrients by plants.

SOURCE OF NUTRIENTS (AND TOXIC ELEMENTS)

The rhizosphere also defines the soil volume from which plants take up mineral nutrients. In order to provide adequate supply of each essential nutrient, the plant can adjust the root architectural form and/or increase the uptake capacity. These modifications in soil-grown plants may occur at the local rhizosphere scale.

Roots can also modify the pH and redox state of the rhizosphere, thus altering the solubility of some nutrients.

Limitation in nutrient availability, as well as excessive availability of toxic elements, can be overcome by release from the roots of low-molecular-weight compounds, which include carboxylates, amino acids, and phenolic compounds. These processes can be greatly enhanced by adverse soil conditions.

Although genotypical differences have been observed in the capacity to acquire limiting nutrients and release of exudates from the roots, it has to be taken into account that these solutes can undergo microbial degradation, enzymatic breakdown, or sorption by soil colloids. Thus, the effectiveness of root exudates appears to be dependent on
the spatial and temporal characteristics of exudation[5] and possibly on the presence of some protection provided by the spatial arrangement of root and soil surfaces.

ROOT-MICROBES: INTERACTIONS AND MOLECULAR SIGNALS

During their growth in natural conditions, plants continuously interact with soil microorganisms.

Microbial population in the rhizosphere may be one or two orders of magnitude higher than that of the bulk soil. Some of these microbes are deleterious, while others are beneficial to plants.[10]

Root colonization is dependent on the release of root exudates. On the other hand, it has been demonstrated that root exudation can be stimulated by microbial colonization of plant roots and by the presence of microbial metabolites, the effects of microbes being species-specific.

Due to differences in rhizodeposition, not only different plant species but also different parts of the root system of the same plant may have distinctive rhizosphere microfloras,[11] possibly reflecting the utilization profile of root exudates.

Among the beneficial microorganisms, bacteria belonging to Rhizobium or Frankia genera, as well as mycorrhizal fungi, are able to establish a symbiotic relation with their host plant.

It is well known that Rhizobia-legume symbiosis involves a molecular cross talk between the plant and the microbe; recently it has been shown that a similar signaling process might be involved in establishing a symbiosis with endomycorrhizal fungi.

Other rhizobacteria, generally designated as “plant growth-promoting rhizobacteria” (PGPR), stimulate plant growth by producing phytohormones or act indirectly as biocontrol agents through the production of antibiotics and siderophores and even by inducing plant resistance mechanisms.[12]

Saprophytic microorganisms in the rhizosphere are responsible for the decomposition of organic residues and nutrient mineralization/turnover processes.

Many plant-associated bacteria use N-acetylated-homoserine-lactones (AHL) as quorum-sensing signals to control processes that are linked both to host interactions and to survival. Interestingly, exudates from some plants were found to contain AHL signal-mimic molecules. This suggests that molecular signals could also be exchanged between plants and non-pathogenic and non-symbiotic rhizobacteria.

Deciphering the molecular basis of root-microbes interactions is a major challenge for understanding the rhizosphere ecology. This would in turn allow the management of the rhizosphere and possibly offer agro-nomic applications.

The complexity of the rhizosphere and its unique features are emphasized also by the biochemical events and molecular cross talk between host and parasitic plants. It has been shown that compounds released by host roots may act as molecular signals for parasitic plants.[13]

It is worthwhile to say that caution should be used when transferring data obtained using artificial microcosms to the situation occurring in the soil. In fact, any bacterial species living in a mixed microbial population, such as that of the rhizosphere soil, may encounter not only the molecular signal produced by a cell of the same species but also molecular signals produced by cells of different species. The situation is made more complex by the presence of plant molecular signals and by the fact that the same AHL molecule can be used to regulate the expression of different biological processes in different bacterial species. On the contrary, some bacterial species can produce multiple AHLs, each having different effects on the phenotype. In soil, the situation is even more complex because the molecular signals can interact with surface active soil particles through electrostatic interactions, hydrogen bonds, and van der Waals bonds. In addition, molecular signals with anionic groups can be adsorbed by inorganic soil colloids by a ligand exchange mechanism.

ROOT SENSING OF THE ENVIRONMENT

To cope with the uneven distribution of ions in the surrounding root, plants have evolved mechanisms which include expression of transporter genes in specific root zones or cells and synthesis of enzymes involved in the uptake and assimilation of nutrients. Root development can also be significantly modified in response to variations in the supply of inorganic nutrients in the soil. These plant responses are largely controlled by the internal status of the plant. On the other hand, it has been recently shown that this behavior is also dependent on the capacity to locally sense the changes in the external concentration of the nutrient.[14] These evidences support the existence in plants of sensing mechanisms for environmental signal(s) coming from the rhizosphere, including variations in the availability and distribution of nutrients.

INTRODUCTION

The rhizosphere soil is a site of complex interactions among plant roots, microflora, and microfauna. Therefore, all known biochemical reactions of living cells also occur in the rhizosphere soil. Pathways of primary and secondary metabolisms of microbial, animal, and plant cells also occur in the rhizosphere soil, including microbial degradation of natural and man-made recalcitrant compounds (pesticides, synthetic polymers, etc.), nitrification by autotrophic bacteria, or dissimilatory reactions of nitrate and sulfate. However, the biochemistry of rhizosphere soil shows some distinctive properties such as the presence of:

1) a variety of compounds released from roots (exudates, secreted lysates, chelators, and signal molecules) and from rhizospheric microorganisms (signal molecules, antibiotics, antifungal metabolites, toxins, antibiotics, phytostimulators, chelators, etc.), and
2) active enzymes in living root, microbial and animal cells, free extracellular enzymes, and enzymes adsorbed by clays or entrapped by humic molecules. Another peculiar aspect of rhizosphere biochemistry is its metabolism, which is the result of complex microflora-microfauna interactions.

RHIZODEPOSITION AND OTHER PARTICULAR ORGANIC COMPOUNDS IN THE RHIZOSPHERE

Rhizodeposition is the term used to indicate the overall compounds released by plant roots into soil. In addition to compounds of primary and secondary metabolism and polymers (mucilage), plant roots, in response to nutrient stresses, can also release chelators. Thus, grasses produce phytosiderophores under iron deficiency whereas dicotyledonous plants respond by increasing the release of organic acids, acidifying the rhizosphere and secreting reductants to increase iron availability to plants. Under iron deficiency, microorganisms of rhizosphere soil also produce chelators, called siderophores, which have a high affinity for iron; the complex interactions between plants and microorganisms under iron stress have been discussed by Crowley. Microbes interacting with plants can be classified based on their effects on plants, as pathogenic, saprophytic, and beneficial; the latter are also denominated plant growth-promoting rhizobacteria (PGPR). When microorganisms interact with plants, no matter if this interaction is beneficial or pathogenic, they use the same mechanism. The key event in the response of plants to microorganisms is recognition, which can occur through physical interaction or in response to specific compounds (signal molecules) released by the roots of the specific plant species to be infected. Thus, flavonoids and isoflavonoids are specific signal molecules in the legume-rhizobia symbiosis. Different plant species release different organic compounds that vary in their ability to induce or inhibit effective signalling by different soil bacteria.

Other compounds of the rhizosphere soil include antibiotics and hydrogen cyanide produced by plant growth-promoting rhizobacteria for the biological control of plant pathogen; antifungal metabolites are very important for the interactions of bacteria in the rhizosphere. Rhizobacteria can also produce phytostimulators, such as auxin derivatives. Azospirillum, a N2-fixing bacteria, may promote plant growth by releasing phytostimulators rather than by its N2-fixing capacity. Indeed, cytokinins, auxins, and gibberellines have been found in the supernatants of these bacteria.

In addition, as any microbial environment, the rhizosphere is characterized by the presence of signal molecules, which permit bacteria to communicate with cells of the same species and sometimes with other bacterial species. Intercellular signal compounds include N-acyl homoserine lactones, cyclic dipeptides and quinolones, and also volatile fatty acyl methyl esters. Microbial interactions have been studied in laboratory conditions without the presence of plants and soil colloids such as clay minerals and humic molecules. According to Pinton et al., future research is needed to understand how the presence of plants and adsorbing surface-active colloids affects molecular cross talk among microbial cells.

ENZYMES IN THE RHIZOSPHERE

The enzyme activity is higher in the rhizosphere than in the bulk soil due to the higher number and activity of microorganisms, in response to the greater substrate...
availability, and to the release of root-derived enzymes.\[6\] Thus, acid and alkaline phosphatase activities were higher in the rhizosphere soil than in the bulk soil; these enzyme activities increased by approaching to the rhizoplane, whereas organic P concentration was negatively correlated with the increase in the enzyme activities. The inorganic P was depleted as the result of the root P uptake.\[7\] The increases in enzyme activities were very high reaching, as the highest values among the different tested crop plants, 911% and 262% for acid and alkaline phosphatase, respectively.

The main problem in measuring an enzyme activity of rhizosphere soil is to distinguish the site of the various enzymes contributing to the measured enzyme activity. Indeed, enzymes can be active inside a plant, microbial, or animal cell or even in cell debris.\[8,9\] In addition, enzymes not requiring cofactors for their activity, such as hydrolases, can remain active for a short period in the extracellular soil environment unless they are adsorbed by clay minerals or entrapped into humic molecules.\[10,11\] Enzymes can be located in the soil matrix by combining ultracytochemical tests with electron microscopy. Unfortunately, it is problematic to apply these techniques to soil because of the presence of minerals, which are naturally electron-dense; the other problems of these techniques are reactions of the counterstaining compounds, such as OsO\(_4\), with humic molecules or aspecific reactions with the heavy metal component of the enzyme-specific medium.\[8\] In spite of these limitations, Forster and collaborators were capable of detecting acid phosphomonoesterase, succinic dehydrogenase, peroxidase, and catalase in microorganisms of rhizosphere soil.\[8,12\] In addition, acid phosphomonoesterase was also detected in roots, mycorrhizae, and fragments of small (7 × 20 nm) microbial membranes.\[8,12,13\]

The enzymes adsorbed by clay minerals or entrapped into the humic matrix can remain active even under unfavorable conditions for microbial activity, because they are more resistant to thermal and pH denaturation than the microbial enzymes.\[9,11\] A role for these extracellular stabilized enzymes in microbial ecology has been hypothesized; indeed, their presence ensures the extracellular degradation of a series of substrates and decreases the need of microbial cells to synthesize and release extracellular enzymes to carry out these reactions.\[10\] It is noteworthy to say that soil is an inhospitable environment for extracellular enzymes because nonbiological denaturation, adsorption and inactivation, and degradation by proteases all conspire to end the life of the free extracellular enzyme.

A better interpretation of changes in enzyme activities in the rhizosphere soil requires to distinguish the activity of the enzyme stabilized by soil colloids and that of free extracellular or intracellular enzymes.\[11\] Unfortunately, the present assays do not allow distinguishing both enzyme activities.

### METABOLISM OF RHIZOSPHERE SOIL AS AFFECTED BY MICROFLORA AND MICROFAUNA INTERACTIONS

The plant uptake of nutrients such as N depends on the interactions between microflora and microfauna. Microbial growth in rhizosphere soil is promoted by the release of organic materials by plant roots; since the C/N ratio of the root-derived C is higher than the C/N ratio of microbial biomass, a substantial amount of N is immobilized during microbial growth.\[6\] This can result in a temporary decrease in the amount of plant-available N. According to Clarholm,\[14\] this microbial N immobilization is followed by a stimulation of the N mineralization promoted by protozoan grazing, with the release of ammonium, which is taken up by the plant root. The release of ammonium occurs because protozoa have a higher C/N ratio than bacteria. This series of events seems to be confirmed by the increase in protease and deaminase activities observed in the rhizosphere soil.\[6\]

Plants can take up and assimilate several N sources (ammonium, nitrate, urea, amino acids), but the particular form taken up depends on the plant species; thus, tomato growth is inhibited if the ammonium concentration is too high.\[6\] Competition between nitrifiers, heterotrophs, and plants occurs in the rhizosphere soil and can be particularly evident in N-limited systems such as forests. In this case, nitrifiers converting ammonium to nitrate may limit the amount of N immobilized by heterotrophs and favor the N uptake by plant species preferring nitrate to ammonium as a N source.

### CONCLUSIONS AND FUTURE RESEARCH NEEDS

Rhizosphere metabolism includes pathways of animal, microbial, and plant cells. However, the overall metabolism of the rhizosphere soil is peculiar because it reflects the complex interactions among microflora, plant roots, and microfauna. Another distinctive characteristic of rhizosphere soil is the presence of a variety of compounds released from plant roots, microorganisms, and microfauna affecting these complex interactions. The most well-known molecular cross talk is that between legumes and rhizobia. However, future research is needed to understand exchanges of molecular signals between the various microorganisms and plant roots, among microbial cells of the same and different species, and between microbial cells and microfauna. It is also needed to study the effect...
of surface-active colloids on the exchange of these molecular signals. Future research should also be directed in setting up enzyme assays, which allow the distinction of the activity due to enzymes stabilized by soil colloids from that of enzymes present in active animal, microbial, and plant cells.

Rhizosphere: Microbial Populations

James M. Lynch
Forest Research, Farnham, Surrey, U.K.

INTRODUCTION
The rhizosphere—the field of action of plant roots—can be viewed as a trinity whereby the biotic and abiotic factors from the soil, plant, and microbial population interact to determine the population structure and composition of the rhizosphere. The microbiota includes bacteria, fungi, actinomycetes, algae, protozoa, nematodes, and some small mites. This diverse assemblage can be influenced by agricultural practices and is influential in determining the sustainability of agricultural systems. The rhizosphere is the powerhouse of soil microbiological activity and offers major opportunities in soil biotechnology. A major research problem is that only about 5% of bacteria are culturable, and the fungi that are isolated often derive from spores that do not represent the negative states of the organism.

DISCUSSION
The bacterial population of the rhizosphere differs from that in the bulk soil, in terms of both population numbers and composition. It contains large numbers of Gram-negative nonspore formers with a higher proportion of chromogenic and motile forms, and more ammonifiers, nitrifiers, denitrifiers, and aerobic cellulose decomposers. However, it sustains fewer Gram-positive cocci and organisms capable of utilizing aromatic acids than found in the bulk soil. Short Gram-negative rods respond most to rhizosphere conditions, and invariably make up a greater percentage of the rhizosphere microflora than that in the bulk soil population. The three genera Pseudomonas, Achromobacter, and Agrobacterium are examples of the Gram-negative rods that are highly stimulated within the rhizosphere.

Given that rhizosphere exudations and secretions—components of rhizodeposition—serve to enhance and maintain a higher population than that found in the bulk soil, it must also be assumed that there is a high level of microbial competition within the rhizosphere. This in turn enhances selection pressure to select for those microorganisms most suited to the rhizosphere environment. Selection of bacteria whose growth is enhanced by amino acids is a reflection of the amount of amino acids in the rhizosphere environment in comparison to in the environment of bulk soil. In general terms, bacterial populations within the rhizosphere are considered less fastidious than those found outside.

In contrast to the quantitative rhizosphere effect on bacteria, the nature of the effect for fungi is more qualitative with little effect on fungal numbers but an enhanced stimulation effect for certain genera. The imperfect fungi Fusarium spp, which are often pathogenic, are prominent members of the rhizosphere and a common example of this phenomenon, although numerous other genera are represented. There can also be an ecological link between fungal components and the bacterial components of the rhizosphere. The symbiotic mycorrhizal fungi, which can be ectotrophic and endotrophic, are particularly important in effectively increasing the root’s absorbing power to promote the uptake of phosphorus and water.

ROOT COLONIZATION
It is generally understood that the organisms associated with seeds (such as the common fungi (Penicillium spp, Aspergillus spp)) and bacteria contribute very little to the established rhizosphere. The young seedling is first colonized by chance bacteria that first encounter the influence of the developing root, with a more species-stable population establishing as the root matures. The developing root tip and root hairs are commonly free of microorganisms, with bacteria colonizing at sites of lateral root emergence from the main root stem. The rhizosphere effect then increases with the age of the plant, reaching a peak at the height of vegetation and declining as senescence approaches. This is, however, a generalization; specific plant species display peaks at alternative times during their life cycles, with crop species generally exhibiting greater rhizosphere effects than do trees. The most pronounced population increases involve the amino acid-requiring bacteria and other organisms with simple nutritional requirements and rapid growth rates. The dominance of specific bacteria in certain plants is another a phenomenon that has been noted (Fig. 1).

The nature of secretions changes through a root’s life cycle; consequently, the microorganisms that it can
support change. It is considered that most root colonization is triggered as the root tip advances through the soil, with the root tip performing as a slowly advancing source of substrate that serves to stimulate the growth and activity of dormant bacteria within the sphere of its influence. The process of root colonization can be conceptually divided into a series of steps: migration toward plant roots, attachment, distribution along the root, and growth and establishment of the microbial population. A number of microbial traits involved in these steps has been postulated, including chemotaxis, agglutinability, the use of flagella, and the ability to utilize complex carbohydrates. The phenomenon of rhizosphere competence describes the ability of microorganisms to associate with roots; the quantitative measurement of this is the colonization potential. The challenge is to stimulate organisms beneficial to the plant rather than those that are harmful, such as toxin producers and pathogens. In this respect some rhizosphere-competent strains of *Pseudomonas* and *Trichoderma* have proven particularly beneficial in disease control and growth stimulation.

![Fig. 1 The rhizosphere trinity: The interacting factors that determine the environmental conditions of the rhizosphere. (Based on Ref. 1.)](image)

**NUTRIENT CYCLING**

The rhizosphere is an environment created and maintained by the plant at cost to the plant. What benefits does the plant receive from this input of energy? The acquisition of nutrients is the preliminary goal of the investment that plants make in their environmental modifications. Interactions with the microbial populations of the rhizosphere enhance the availability and uptake of nutrients that might otherwise have been unavailable to the plant root system. This happens in a number of ways and for a number of nutrients. Probably the most important nutrient in terms of plant growth is nitrogen, the discussion of which will serve here to also exemplify the importance of other nutrients.

Plant roots and the microbial populations that inhabit them are highly integral to the nitrogen cycle. The microbial population of the bulk soil is involved in the conversion of nitrogen through its various forms in the nitrogen cycle, as well as in fixing free nitrogen from the atmosphere (free-living nitrogen fixers). The enhanced populations within the rhizosphere provide the host plant with nitrogen in a readily available form for immediate utilization and subsequent release when the plant dies or is consumed. Far more nitrogen passes through this link in the cycle than does from the bulk soil.

Nutrient cycling in soil is extremely dependent on the supply of energy to the soil biota. Given that the source of this energy is carbon from organic compounds, it can be seen that the nitrogen and carbon cycles are inextricably linked, with carbon as the impetus.

**MINERALIZATION AND IMMOBILIZATION**

The decomposition of plant material and accompanying mineralization and immobilization of the organic N it contains are key processes in the soil–nitrogen cycle. Once incorporated into the soil matrix, plant residues will bring about a rapid increase in microbial biomass as the material is colonized. In the case of heterotrophic microorganisms using organic material as a source of combined carbon for both respiration and cell synthesis, the progressive decomposition of nitrogen-containing compounds will result in ammonium for use by the organism itself, with the excess released as waste. If insufficient nitrogen is contained within the substrate, then the organisms will draw upon the soil mineral nitrogen, resulting in nitrogen immobilization. The balance between release of nitrogen and immobilization depends on the carbon-to-nitrogen ratio of the material under decomposition, the energy efficiency of the organism, and the carbon-to-nitrogen ratio of the cells being synthesized. The carbon-to-nitrogen ratio of the substrate is the most influential of these factors, with materials varying from 5:1 for animal wastes to 100:1 for cereal straws. The ratio at which nitrogen is neither released nor immobilized has been shown to be approximately 35:1. This highlights the importance of this microbial-mediated process as it supplies nitrogen to the plant in what can be considered its preferred form (which is a less susceptible form than leaching) as well as providing the raw material for the nitrification sequence.
Given that ammonifying bacteria have a higher rhizosphere population than the bulk soil or R:S ratio (in excess of 50:1), it would be expected that there would be greater mineralization of organic matter within the rhizosphere. In the field situation, however, less mineralization can be shown to have occurred in soil under crops than in fallow soil, even allowing for the nitrogen taken up by the plants. This anomaly can be explained by $^{15}$N studies that have shown that, although the net amount of mineralization in cropped soil is only half that in fallow soil, the total quantity mineralized is greater under cropping. The difference between the two soil types is due to the rapid assimilation of the mineralized matter by the microbiota within the rhizosphere of the crop.

This illustrates that the availability of nitrogen to the plant is a result of the opposing processes of mineralization and immobilization and on the plant’s ability to compete for the available nitrogen. This suggests that the overall microbial effect in the rhizosphere is detrimental as often as it is beneficial. However, experimental comparisons of rhizosphere and nonrhizosphere soils have demonstrated that the rhizosphere effect on the net N mineralization from indigenous soil organic matter is positive in many cases but not in all.\(^{[10]}\) The actual microbial N immobilization generated by root-derived carbon seems to be counterbalanced by stimulation of nitrogen mineralization by promoted grazing of protozoa and the consequent release of ammonium by assimilation, as well as a higher microbial turnover of soil organic matter. It is hypothesized that the effect can also be beneficial, as a consequence of the nitrogen form involved (nitrate), and because the continual cycling of the nitrogen compounds via the microbial components prevents their loss from the system through leaching, thus providing a more constant supply to the plant. 

*Pseudomonas fluorescens* is a very common soil bacterium; some strains can increase the mineralization of nitrogen in the pea rhizosphere, but reduce it in wheat.\(^{[13]}\) The likely interpretation is governed by the differential effects in the two rhizospheres on the bacterial-feeding nematodes and protozoa.

**DINITROGEN FIXATION**

The biological fixation of molecular nitrogen is carried out by several free-living bacterial genera, some of which are rhizosphere-associated, such as other *Azotobacter* and *Azospirillum*.\(^{[12]}\) In terrestrial systems, however, the largest contribution of combined nitrogen comes from the symbiotic fixation of dinitrogen by rhizobia, with fixation rates often two to three orders of magnitude higher than those exhibited by free-living bulk soil dinitrogen fixers. It is the increase in plant-available nitrate that is the most consistent effect on soil nitrogen levels brought about by both crop and pasture legumes. A combination of conserved soil nitrogen, greater mineralization potential, and the return of fixed nitrogen explain why the benefits of crop legumes to nonlegume crops can be considerable.

The best studied examples of symbiotic nitrogen fixation are the soil bacteria of the genera *Rhizobium*, *Bradyrhizobium*, and *Azorhizobium*, collectively referred to as rhizobia. These organisms have the ability to induce the formation of nodules on the roots of leguminous plants. In these nodules the host plant provides the bacteria with their nutrient requirements and an environment conducive to nitrogen fixation. In return, the bacteria fix dinitrogen in excess of their requirements. The dinitrogen is subsequently released as ammonia and taken up by the plant.

While the rates of N\(_2\) fixation for free-living bacteria are relatively low in comparison to those in a symbiotic or mutualistic relationship, the bacteria that conduct fixation under such conditions are widespread in soils, so do contribute to soil nitrogen inputs. This said, the rate of free-living bacteria such as *Azotobacter* and *Azospirillum* is increased under rhizosphere conditions, due to increased efficiency as a result of more readily available organic compounds exuded from roots. Consequently, it can be seen that the symbiotic fixing of N\(_2\) in the rhizosphere brings substantial benefit to the plant system’s ability to acquire and utilize nitrogen.

**CONCLUSION**

The rhizosphere community is a very complex structure that has great metabolic diversity. Some of this diversity can be beneficial to plants and the environment, although other facets are harmful. The population can now be investigated at the molecular level by determining nucleic acids present. The challenge is to link conventional population biology and metabolic diversity to this genetic capability. The study of the functional genomics of the rhizosphere provides tantalizing prospects for the future.

*Rhizosphere Management: Microbial Manipulation for Biocontrol*, p. 1098
REFERENCES

INTRODUCTION

The rhizosphere is the region of soil surrounding a length of root that is modified physically, chemically, or biologically by the activity of the root. Root activity may include water and mineral nutrient uptake, release of water-soluble organic solutes, production of mucilage, sloughing of plant cells, etc. Uptake/release perturbs the ‘‘steady-state’’ concentrations in bulk soil and generates gradients leading to transport through the soil matrix. The rhizosphere, in modeling terms, is therefore defined as an approximately cylindrical region of variable radius, encompassing a concentration gradient of the solute(s) of interest. Rhizosphere models simulate the often complex and dynamic changes in the chemistry and microbiology of this region that occur over time.

MODELING SOLUTE TRANSPORT IN THE RHIZOSPHERE

The common feature of all mechanistic rhizosphere models is the simulation of the transport processes that move solutes around the rhizosphere. The physical processes involved are diffusion and convection, and the former is normally the dominant process.1

Diffusion of Solutes

The development of the theory of solute diffusion in soils was largely due to the work of Nye and his co-workers in the late 1960s and early 1970s2 who adapted the Fickian diffusion equations to describe diffusion in a heterogeneous porous medium. Fick’s law describes the relationship between the flux of a solute (mass per unit surface area per unit time, \( J_L \)) and the concentration gradient driving the flux. In vector terms

\[
J_L = -D_L \nabla C_L
\]  

where \( D_L \) is the diffusion coefficient in pure water at the ambient temperature and pressure, and \( C_L \) is the concentration of the solute in solution. For a solute diffusing in soil, three additional factors must be taken into account:2 firstly, diffusive movement is only significant in the solution phase and only concentration gradients in the soil solution drive diffusive movement; secondly, the cross-sectional area available for diffusion is reduced because the solute can only move in the solution phase; thirdly, an empirically determined tortuosity factor \( f \) (range \( 0–1 \)) is required to reflect the increased pathlength for diffusion in soil. To account for these factors, which all act to reduce the rate of diffusion in soil compared to water, Fick’s law is modified:

\[
J = -D_L f \theta \nabla C_L \tag{2}
\]

where \( \theta \) is the volumetric moisture content and \( C_L \) defines the soil solution concentration of the solute.

In most cases \( C_L \) is not known directly but is a secondary, derived parameter, and to solve Eq. 2, it must be related to a known variable. This introduces a complication because many solutes exist in several forms in soil and some do not contribute directly to diffusion. Conventionally, all phases that can equilibrate with soil solution over a time-scale comparable with diffusion (seconds–minutes) are defined as available solutes (\( C_a \)) and are considered to contribute to diffusion. This would include most anions in most soils and uncharged organic molecules such as glucose. Many solutes display positive charge and will interact electrostatically with the negatively charged surfaces found in most soils, whereas others, such as phosphate, may interact with surfaces via ligand exchange mechanisms. Such inner and outer sphere surface complexes,3 jointly termed exchangeable solutes, are normally included as available solutes.

The reciprocal of the buffer power, \( b \), defines the fraction of the available solute which is in soil solution at a particular concentration, i.e.,

\[
b = \frac{\partial C_a}{\partial C_L} \tag{3}
\]

Substituting for \( C_L \) in Eq. 2 gives

\[
J = -\frac{D_L \theta f}{b} \nabla C_a \tag{4}
\]

The relative rate of movement of individual solutes in soil is therefore dominated by the value of their buffer power. Buffer power is normally derived experimentally by adding different amounts of solute to a soil, allowing a brief equilibration period, and then determining the new soil solution concentration: \( b \) is then the gradient of the
resulting buffer curve. For mineral ions, the values for \( b \) vary enormously between soils, but typical values might be 100–2000 for phosphate, 3–30 for K and NH₄, while for anions such as NO₃ and Cl, which exist wholly in the solution phase, \( b = 0 \). Organic solutes show similar ranges. As a consequence phosphate may diffuse 5000 \( \times \) slower than nitrate in the same soil.

Convective Transport

Water, moving through the soil pores in response to water potential gradients, moves with it the solutes dissolved in soil solution. In a rhizosphere context, water moves radially toward the root to replace water taken up by the roots for transpiration. The flux of solute due to water movement \( (J_w) \) is simply the product of the rate of water flow at that point and the concentration in soil solution:[2]

\[
J_w = vC_L = \frac{v}{D} C_a
\]  

(5)

In a cylindrical system, because equal amounts of water are being transported across successive concentric radial increments, the rate of flow of water must vary across the rhizosphere, with the fastest flows at the root surface. It is conventional to use a single parameter for rhizosphere water flow, \( v_0 \), which is defined as the water flux (volume per unit area per unit time) at the root surface, \( r_r \).

Continuity Equation for Solute Transport

To describe the movement of solutes in the rhizosphere, where concentration gradients change with space as well as time, \( t \), mass conservation is invoked with the spatial geometry appropriate for the cylindrical root:[2]

\[
\frac{\partial C_a}{\partial t} + \frac{1}{r} \frac{\partial}{\partial r} \left[ r D_0 f \frac{\partial C_a}{\partial r} + r_0 v_0 \frac{r}{b} C_a \right] = \pm \frac{\partial S}{\partial t}
\]  

\( r_a < r < r_b \)

(6)

Here the spatial coordinate, \( r \), defines the radial position in the cylinder of soil surrounding the root. This parabolic, second-order partial differential equation describes how the concentration of available solute at an arbitrary point in the rhizosphere changes with time in response to the concentrations on either side of it. Note that this equation is effectively one-dimensional because concentration gradients along the root length can be neglected on the basis that roots are long and thin and concentrations around the root are assumed to be radially symmetric.[1] If concentration gradients along the root are thought to be important, then two-dimensional equations and solutions are required.[5]

Transfers between available and unavailable solutes are modeled via the \( \partial S/\partial t \) source-sink term: these could include dissolution of sparingly soluble mineral phases; the mineralization of soil organic matter forms of the solute or the immobilization into microbial biomass.[1–3]

Boundary Conditions

Eq. 6 describes how solutes will move in response to concentration or water potential gradients formed when the rhizosphere is perturbed by the activities of the root. These activities need to be mathematically described and form one of the two boundary conditions required to solve the initial-value problem: two examples are given below. The first is commonly used to simulate the uptake of mineral nutrients and equates root uptake \( (I_{\text{max}} = \text{maximum rate of uptake per unit surface area of root}, K_m = \text{affinity constant for uptake}, E = \text{rate of loss of nutrient to the soil per unit surface area}) \) to the diffusive flux at the root surface.

\[
I_{\text{max}} \frac{C_L}{C_L + K_m} - E = \frac{D_0 f}{b} \frac{\partial C_a}{\partial r} \quad \text{at} \quad r = r_a
\]

(7)

The second describes the efflux and subsequent influx of glucose from roots that forms part of the rhizodeposition of root C that leads to microbial accumulation around roots:[2]

\[
-P(C_{cyt} - C_L) + V_{\text{max}} \frac{C_L}{C_L + K_m} = D_1 f \frac{\partial C_a}{\partial r} \quad \text{at} \quad r = r_a
\]

(8)

Here, efflux depends on diffusion (\( C_{cyt} \) and \( C_L \) are the glucose concentrations in the root cytoplasm and soil solution, respectively, and \( P \) describes the permeability of the root to glucose). Uptake of C is described in terms of Michaelis–Menten parameters.

The outer boundary condition defining the limit of the rhizosphere at \( r = r_b \) is normally of the form:

\[
\frac{\partial C_a}{\partial r} = 0 \quad \text{at} \quad r = r_b
\]

(9)

Solution of the Equations

The partial differential equations (PDE) given in Eqs. 6, 7 or 8, and 9 together form an initial-value problem, and initial values for all parameters and concentrations in the region \( r_a \) to \( r_b \) must be specified at the start. Most equations are then solved numerically using finite difference or finite element methods.[5]

Several commercial mathematical packages now offer PDE solvers although some may impose restrictions on the type of boundary condition that can be specified. In some cases, approximate boundary conditions can be specified which allow for an analytical solution.[1,2]
MORE COMPLEX SYSTEMS

The rhizosphere is a complex environment with multiple simultaneous interactions occurring between roots, soil, and microbes.[2,7,8] As the rhizosphere develops, microbe numbers and individual species abundance may change markedly, the soil environment in terms of structure and chemistry, e.g., soil pH may be modified, and the levels of mineral nutrients, water, and organic compounds will change. This in turn may affect other processes leading to multiple feedback effects. Rhizosphere models accommodate this complexity by including several process variables, each with their own continuity equation and boundary conditions, which interact with each other through source-sink terms. The set of equations is then solved simultaneously. For example, the transport and uptake of Ca, Mg, K, NO₃, Cl, and SO₄ were simulated simultaneously to predict soil pH change in the rhizosphere resulting from imbalanced cation and anion uptake.[9]

SCALING

A plant root system may extend several tens of kilometers and may take months to develop. The extent, deployment, and architecture of the root system will depend in part on the mineral nutrition resulting from the integrated uptake from each root segment and its local rhizosphere. Rhizosphere models of growing plants must therefore integrate from the local rhizosphere level to the whole plant scale. This may simply involve integrating influx over the growing root system if mineral nutrients do not limit growth.[1,6] However, increasingly, the rhizosphere model is a subprocess model within a larger simulation of whole plant growth where root parameters depend on nutrient uptake history,[2,10] although most whole plant or crop models currently simplify the rhizosphere model.

CONCLUSION

The biological members of the rhizosphere trinity show enormous capacity for adaptive “plastic” responses to changing environmental conditions. Plants under nutrient stress can show a variety of plastic responses including changing root allocation, architecture, physiology, and biochemistry,[7] many of which have not been comprehensively modeled. Attempts to manipulate the microbiology of the rhizosphere[8] depend on favoring one or two species to achieve biological control, yield promotion, or bioremediation: modeling of microbial dynamics at the species level will represent a considerable challenge in the future.

INTRODUCTION
The absorption of nutrients by plant roots is the process by which nutrients enter root cells across the plasma membrane. For soil-grown plants and most nutrients, it is considered that the limiting step in plant nutrition is not the absorption, but rather the processes occurring in the rhizosphere prior to absorption, namely nutrient mobilization and movement. The acquisition of nutrients embraces all these major steps, which depend on physical, chemical, and biological processes and factors.

BIOLOGICAL PROCESSES AND FACTORS INVOLVED IN NUTRIENT ACQUISITION
The acquisition of nutrients by plants combines three strategies. The first strategy is to increase the surface of absorption, which is essential for the acquisition of poorly mobile nutrients such as P and micronutrients. The architecture of the root system is one of these means: Its diversity and plasticity among plant species show that this strategy is differently exploited. The actual surface of absorption is not simply the external surface developed by root system: Root hairs are extensions of epidermal cells that can considerably extend the surface of absorption and the actual volume of soil prospected by roots. Their quantitative influence on the acquisition of P has been clearly demonstrated. In addition, nutrients such as Ca and Mg move through the apoplasm of root cortex before actually being absorbed. Thus, the surface developed by the apoplasm should be taken into account, although it does not contribute to enlarge the volume of prospected soil. Another extension of the surface of absorption is provided by the symbiosis with mycorrhizal fungi, which is a widespread feature as more than 90% of plant species can form such symbiosis. Mycorrhizal hyphae have much finer diameter than roots and root hairs and can extend several centimeters from the root surface, providing access to nutrients that would otherwise not be spatially available to the root. Their importance for the acquisition of poorly mobile nutrients such as P has been demonstrated. The actual volume of the rhizosphere therefore depends on these complex features of the geometry of roots and mycorrhizae.

The second strategy involved in the acquisition of nutrients relies on the physiological equipment of the absorbing surface, i.e., transporters and ion channels of the membranes of root hairs, epidermal and cortical cells, and those of mycorrhizal hyphae in mycorrhizal plants. Their density and absorption characteristics largely determine the plant’s capability to acquire nutrients. For many nutrients that occur at rather low concentrations in the soil solution, uptake systems exhibiting a high affinity and able to function at low concentrations are crucial for the plant’s acquisition efficiency. The absorption is, however, often considered to be nonlimiting, compared with the physical and chemical processes involved in the mobility of nutrients in the soil. The third strategy of the plant for acquiring nutrients relies indeed on physical and chemical processes that affect the availability of nutrients in the rhizosphere.

PHYSICAL PROCESSES AND FACTORS OF NUTRIENT MOVEMENT
Plant roots are taking up mineral nutrients dissolved in the soil solution. Therefore, in the absence of any movement of nutrients in the soil, the roots can access only a minor amount of nutrient from soil solution in the immediate vicinity of roots. This process, called root interception, is therefore considered to contribute only a minor proportion of the overall acquisition of most nutrients. In addition to this process, the uptake of water by roots results in a movement of water from the bulk soil towards the root surface, along a gradient of water potential. As the soil solution contains water and dissolved nutrients, the uptake of water by roots generates a convective movement of solutes, i.e., mass-flow. The corresponding flux of nutrient depends on the flux of water and nutrient concentration in the soil solution. For those nutrients that are present at elevated concentrations in the soil solution, which is typically the case of nitrate in many agricultural soils, mass-flow can contribute a major proportion of plant acquisition. For Ca and Mg, it can even exceed the actual flux of nutrients absorbed by the plant, thereby resulting in a buildup of their concentration in the rhizosphere. This may ultimately result in a precipitation of Ca salts around roots, such as CaCO3 in calcareous soils.
On the contrary, for those nutrients that are present at low concentrations in the soil solution compared with the plant’s requirement, such as K and P (Table 1), root absorption results in a decrease in concentration in the rhizosphere (Fig. 1). The resulting concentration gradient in the rhizosphere is the driving force for diffusion. The diffusive flux of nutrient also depends on the diffusion coefficient.\[2,6\] The actual diffusion of any nutrient in soils is, however, much slower than in water, because of physical and chemical interactions with the soil solid phase: [8] The soil water content, tortuosity, and buffer power (ability of soil solid phase to replenish the soil solution) determine the effective diffusion coefficient in soils.\[2,9\] Table 2 shows that whereas the diffusion coefficient in water is fairly similar for ions such as NO$_3^-$, K$^+$, and H$_2$PO$_4^-$, their diffusion coefficient in soils is different because of the lower mobility of K$^+$ ions, and more so of H$_2$PO$_4^-$ ions compared with NO$_3^-$ ions. Such differences are essentially due to differences in buffer power that arise from chemical interactions with soil constituents. H$_2$PO$_4^-$ ions are prone to strongly react with soil solid phase, via a whole range of precipitation/dissolution and adsorption/desorption reactions, while NO$_3^-$ ions are not. The buffer power of soils for H$_2$PO$_4^-$ ions is thus much larger than for NO$_3^-$ ions, and hence their effective diffusion coefficient is much smaller (Table 2). Therefore, the radial distance from which a nutrient can diffuse towards the root surface considerably varies among nutrients and soils (Table 2)—from centimeters for NO$_3^-$ ions and millimeters for K$^+$ ions to a fraction of a millimeter for H$_2$PO$_4^-$ ions (Fig. 1). The physical factors that influence the movement of nutrients towards the root surface via both mass-flow and diffusion are soil water content, porosity, tortuosity, viscosity, and temperature. All but the last can be altered by roots (Fig. 2).

### CHEMICAL PROCESSES AND FACTORS INVOLVED IN NUTRIENT AVAILABILITY

The acquisition of nutrients is much dependent on chemical processes and factors that determine the actual concentration and speciation of nutrients in the soil solution and the soil buffer power. These vary with nutrients, soil types, and properties and as a consequence of root and microbial activities in the rhizosphere.

The uptake activity of the root can result in considerable changes in nutrient concentrations, which can either increase or decrease in the rhizosphere (Fig. 1).

Copyright © 2004 by Marcel Dekker, Inc.
This will have a dramatic effect on all the reaction equilibria governing the dynamics of nutrients in soils.\(^7\) It has been estimated that the concentration of K decreases 100–1000-fold in the rhizosphere, shifting dramatically the equilibria of adsorption/desorption of exchangeable K and even fixation/release of nonexchangeable K.\(^{10}\) This explains the rapid depletion of exchangeable K and substantial contribution of nonexchangeable K to K availability in the rhizosphere (Fig. 3), which would not occur under bulk soil conditions.\(^{10}\)

The availability of many nutrients such as P and metal micronutrients (Fe, Mn, Zn, Cu, etc.) is strongly pH-dependent, as protons are implied in their speciation and in many reactions, e.g., precipitation/dissolution at the soil solid–soil solution interface. Roots and rhizosphere microbes can be responsible for considerable changes of pH and, hence, of the availability of nutrients such as P.\(^5\) The origins of root-induced pH decrease are as follows: 1) primarily proton release to counterbalance an excess of cation over anion uptake; 2) release of organic acids; and 3) release of CO\(_2\) via respiration, which leads to a buildup of rhizosphere concentration of H\(_2\)CO\(_3\), which dissociates in all but acid soils.\(^7\) The availability of Ca phosphates can be much increased as a consequence of the lower rhizosphere pH found in ammonium-fed plants than in nitrate-fed plants.\(^5\)

**Fig. 2** Schematic diagram of the physical, chemical, and biochemical interactions between roots and soil components that determine the movement and availability of nutrients in the rhizosphere. Note that the microbial activities that are stimulated by root exudation themselves comprehend physical (e.g., aggregation), biochemical (e.g., mineralization), and chemical (e.g., chemical reactions related to microbial respiration or release of acids) processes. Although of equal importance, they have not been drawn for the clarity of the diagram. (View this art in color at www.dekker.com.)

**Fig. 3** Depletion of exchangeable K in the rhizosphere of oilseed rape after four days of growth in a fertilized and nonfertilized soil sampled at the long-term fertilizer trial of Gembloux, Belgium. The extension and intensity of the depletion zone were used to calculate the amount of exchangeable K depleted by the plants. Subtracting this value from the actual amount of K taken up (determined by plant analysis) provided an estimate of the contribution of the release of nonexchangeable K within the four days of the pot experiment.
The availability of many metal micronutrients is also governed by redox reactions and complexation processes, which can be considerably affected by the activities of roots and microbes in the rhizosphere. Complexing compounds released by roots and rhizosphere microbes have been shown to potentially increase the availability of metal nutrients. Grasses are capable of releasing Fe-chelating compounds called phytosiderophores. This process is enhanced under Fe deficiency and is thus part of an efficient strategy to acquire Fe in soils where its availability is minimal, such as calcareous soils. These root exudates can also strongly chelate other metal micronutrients such as Zn and Cu and thereby increase their availability. Carboxylic anions have also been extensively studied for their role in the dynamic of nutrients such as P. Their effect is based on the complexation of metal cations that play a major role in binding phosphate ions in soils, such as Ca, Fe, and Al, but can also rely on ligand exchange reactions that promote the desorption of phosphate ions from soil constituents. In many plant species, the rate of release of such exudates may be too low to be of any significance, though. Some species of plants and ectomycorrhizal fungi have been shown to exude large amounts of citrate, malate, or oxalate and significantly increase the availability of soil P. Some major nutrients can occur in the soil as organically bound nutrients, such as N, P, and S. These organic molecules will require biochemical processes such as enzymatically controlled hydrolysis to evolve into smaller molecules and ultimately release N, P, and S. Plant roots can exude some enzymes that will catalyze such breakdown processes, as shown for phosphatases that help plants make use of organic P compounds. However, soil microorganisms play a major role in these processes, through a variety of enzymatic pathways. Their stimulation by root exudation definitely contributes an enhanced release of organically bound nutrients in the rhizosphere (e.g., phosphatases, proteases, aminases produced by ectomycorrhizal fungi). Fig. 2 summarizes the numerous root-mediated, biochemical, and chemical processes and factors that determine the availability of nutrients in the rhizosphere.

CONCLUSION

Measuring the peculiar properties of the rhizosphere is challenging because of its spatial and temporal dynamics. Considerable advances in the identification of the factors and processes that determine the availability of nutrients in the rhizosphere have been made in recent decades, though. Comparing model outputs with actual measurements often shows large discrepancies, which suggest that there is still a need to better quantify the processes involved in nutrient acquisition. Another challenge for future research is to make better use of such knowledge to determine how to manage those rhizosphere processes to improve a plant’s acquisition efficiency, growth, and health. Both microbial and plant components are important tools to do so, in order to minimize the inputs of fertilizers and pesticides and increase the sustainability of plant-based productions.

INTRODUCTION

Rice is one of the most important cereal crops in the world because it is the main staple for about half of the world’s population. Rice is also one of the most extensively analyzed plants in terms of its molecular biology, genetics, and nearly complete genome sequence and is thus considered a model plant for the cereal crops. Recent technological advances in genome analysis, such as high-throughput genome sequencing and genomewide analysis of transcripts, have paved the way for the characterization of many of the genes expressed in response to various environmental stresses. These innovations are expected to accelerate the breeding of new rice varieties with high yields and adaptability to unfavorable environmental conditions, thereby ensuring sufficient food to feed a burgeoning population, particularly in Asia and Africa. For this purpose, a thorough understanding of the rice plant’s complex biological pathways, such as the genetic mechanisms of reproduction and physiological mechanisms of flowering time, is of utmost importance. In this article, the recent progress in rice molecular genetics is reviewed with emphasis on the development of rice genomics and its applications in the future.

MAPPING THE RICE GENOME

CLONE-BY-COLNE

A molecular genetic analysis of rice has been undertaken to dissect the rice genome using DNA markers such as RFLP (Restriction Fragment Length Polymorphism), SSR (Simple Sequence Repeat), AFLP (Amplified Fragment Length Polymorphism), or CAPS (Cleaved Amplified Polymorphic Sequence). As a result, a high-density and precise genetic map with RFLP markers is now available,[1] and soon these markers will be converted to PCR-based markers using the genome sequence information to facilitate wider applications. In addition, a new kind of marker based on SNP (Single Nucleotide Polymorphism) or In/Del (Insertion or Deletion of nucleotide) generated by comparison of nucleotide sequences among rice varieties or rice subspecies will also become available soon using the genome sequence data. DNA markers are extremely useful in determining the precise allocation of target genomic region within the genome, particularly in gene isolation by map-based cloning.[2] Also, DNA markers are indispensable in ordering large insert clones for construction of a sequence-ready physical map of the genome.[3]

Physical maps of the rice genome have been established using genomic DNA fragments cloned in YAC (Yeast Artificial Chromosome), BAC (Bacterial Artificial Chromosome), or PAC (P1-derived Artificial Chromosome). At the Rice Genome Research Program (RGP), a YAC-based physical map covering 80% of the whole rice genome has been constructed by combining the results of RFLP marker and EST (Expressed Sequence Tag) screening.[5] Initially, a skeleton YAC physical map with 63% coverage was constructed using 1439 RFLP markers in the genetic map.[5] Thereafter, the 3’ untranslated, unique sequences of rice ESTs were used as PCR primers to screen the YAC library and assign corresponding clones to previously mapped YAC contigs. As a result, YAC clones that carried both mapped and unmapped ESTs were newly allocated on the chromosomes so that the YAC contigs were extended and the genome coverage was increased to 80%.[4] By mid-2002, this YAC-based physical map contained 6591 ESTs, and it is highly informative for map-based cloning. For example, the gene corresponding to rice dwarfism, d1, is one of the genes that has been cloned and characterized by this approach.[6]

The rice physical map for genome sequence analysis has been constructed with BAC or PAC clones using methods for identifying overlaps and contiguous clones. In order to assign the clones to specific regions of the chromosome, fingerprinting by restriction enzymes is generally used. The fingerprint data obtained by electrophoresis is then analyzed by an fpc (fingerprinted contigs) program[7] under an empirically adopted condition to make correct assignments of clones and overlaps. In this method, it is necessary to confirm the true overlaps by two parameters involved in fpc, namely, tolerance and cutoff values. These two parameters determine whether the contigs are reliable or not. A rice physical map based on fingerprints has been constructed at Clemson University Genomics Institute.[8]

Clones were first assigned to their chromosomal positions by using the DNA markers described above. The availability of many PCR-based DNA markers
facilitated accurate anchoring of BACs/PACs by PCR prior to fingerprinting. The RGP screened Nipponbare PAC and BAC libraries with EST markers assigned on each of the 12 chromosomes. For example, in the case of chromosome 1, about 900 kinds of PCR primers were used for screening, and the fingerprint data of the anchored BACs/PACs were used for estimation of the overlaps among them. By this procedure, about 80% of chromosome 1 has been covered by BACs/PACs.

The physical map can be further refined using sequence information of the anchored clones. For this purpose, a database of BAC/PAC end sequences was established. CUGI has sequenced both ends of 92,000 BAC clones to help select the next target clone for sequencing among the aligned and mapped clones. This procedure is also useful to fill gaps on the RGP’s physical map. Additionally, the accuracy of the physical map is determined by the consistency of the sequences of aligned clones.

Rice genome sequencing is performed by an international consortium, the International Rice Genome Sequencing Project (IRGSP), in which 11 countries contribute to generate a high-quality sequence (99.99%) of the 12 rice chromosomes. The genome sequence data are accessible through a centralized database named INE (INtegrated rice genome Explorer) working by Java applet. Users of INE can find a PAC/BAC clone mapped to its chromosomal location by DNA markers and see the result of the annotation of the corresponding PAC/BAC sequence. Annotation of the sequence is performed using an automated annotation system, RiceGAAS (Rice Genome Automated Annotation System), which combines the results of both gene prediction and similarity search programs to assign the location of predicted gene and its function. Manual curation is also performed to come up with the most plausible gene model. The annotation map for each sequenced clone can be viewed graphically through INE, and each predicted gene is shown with the complete coding and protein sequence as well as a list of similar genes with information from the nonredundant protein database of NCBI. Two other databases, Oryzabase and Gramene, have been developed to show rice genetic resources and morphology and to integrate cereal genome information based on annotated rice genome sequence and associated biological information, respectively.

WHOLE-GENOME SHOTGUN SEQUENCING

In contrast to the clone-by-clone strategy of constructing a physical map to organize the DNA sequence, an alternative inexpensive and rapid strategy has been recently applied to the rice genome. This is called a whole-genome shotgun sequencing and involves the sequence analysis of a large number of randomly chosen, small-insert clones to provide enough data for assembling the entire genome. However, because of the high complexity of the rice genome, it is impossible to make the correct assignment of a large number of short contigs without additional information, such as positional information of specific markers. Furthermore, many repetitive sequences in the genome were not assembled, and the gaps between contigs would be difficult to fill with this strategy. Therefore, supplemental data such as BAC-end sequences and a reference to the standard genome sequence by IRGSP are indispensable to raise the quality of sequence data obtained by a whole-genome shotgun method.

GENETIC AND REVERSE-GENETIC METHODS

Functional analysis of rice genes is mainly by genetic and reverse-genetic methods and is greatly aided by genome sequence data. So far, about 500 phenotypes have been assigned to 12 linkage groups, and about 200 of them have been genetically positioned on 12 chromosomes. In addition, many mutants generated by chemical mutagens, such as N-methyl-N-nitrosourea, and by rice endogenous retrotransposon, such as Tos17, have been used as resources for gene isolation. Among the genomically important genes isolated using these strategies are the bacterial blight resistance genes, Xa1 and Xa21, the rice blast resistance genes, Pi and Pi-ta, the gibberellin-insensitive dwarf gene, d1, the constitutively gibberellin-responsible slender rice gene, slrl, and the viviparous mutant genes, Osabal and Ostact. In particular, Tos17 is an advantageous tool because it has a high probability of being inserted into gene-rich regions, and the insertion site sequences are easily identified by analyzing the flanking sequence of the Tos17 insert with suppression PCR. The disrupted gene sequence can be easily identified by referring to the genome sequence, and the data of resultant phenotype indicate the disrupted gene function. The insertion lines containing Tos17 are also used for reverse-genetics methods to identify gene function. PCR screening of large populations of Tos17 insertional mutants by gene-specific primers often find out target mutant. This strategy has been successfully used to identify the function of rice homeobox gene, OSH15, and phytochrome A.

The genes isolated as described above have strong phenotypes to facilitate isolating the responsible gene. However, most genetic variation seen in the field doesn’t show such disruptive phenotypes. Natural variants show differences in most plant traits including flowering time, clump height, grain weight, and number of seeds. These
traits are generally important in agronomy and are called quantitative trait loci (QTL) or polygenic traits. Before the introduction of molecular tools for genetic analysis, it was difficult to isolate genes responsible for these traits. However, a combination of marker-assisted selection and advanced backcrossing methods makes it possible to isolate each component of a target QTL as a single Mendelian factor similar to the isolation of the mutant genes described above.\[32\] This strategy has been used for the identification of genes identified as a QTL for rice flowering time.\[33,34\] At least 14 loci were detected as QTLs of flowering time using progenies derived from a cross between a japonica variety, Nipponbare, and an indica variety, Kasalath. Among them, seven loci were identified as photoperiod sensitivity genes, and the structure and function of three of these genes were elucidated by map-based cloning followed by transformation. They are homologues to zinc-finger protein \textit{CONSTANS},\[35\] protein kinase \textit{CK2\alpha},\[36\] \[3\] and flowering time \textit{FT}\[34\] genes found in \textit{Arabidopsis}. However, these homologous genes appear to have opposite functions: Flowering is triggered under short day-length conditions in rice and under long day-length conditions in \textit{Arabidopsis}. This indicates the existence of a clock gene in both plants, yet to be identified.

**CONCLUSION**

With its small genome size, rice is considered the prototypic cereal genome. Recent findings show that because of the considerable syntenic relationships between all the cereals, the homologues of rice genes can be anticipated to be found at analogous chromosomal positions in other grass species.\[37\] Recognition of these relationships has led to the exciting prospect that rice can be used to understand much of the genomic arrangement of the economically important cereals. However, a more detailed comparison of genomic sequences and gene function is necessary to clarify the syntenic relationships among cereal crops. Since the birth of the ancestral cereal plant about 60 million years ago, each species has diverged to its present nature by modifying the ancestral genes to fit its lifestyle. Understanding the similarities and differences among cereal genes using rice as a reference plant may be the key in establishing how gene families diverged and how biological pathways have been modified in the course of evolution.

Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

Rice blast is considered to be the most important disease of rice throughout the world. The disease occurs in 85 countries and can be very destructive when environmental conditions are favorable. Despite the extensive use of resistant cultivars and various fungicides, disease epidemics continue to occur in most rice-growing areas, and the annual loss to rice blast is estimated to be about US$5 billion worldwide. As rice remains the major food crop for about half of the world’s population, rice blast is recognized as one of the main pathological threats to world food supplies. A better understanding of the processes and mechanisms of pathogenesis will be helpful for an effective control of the disease.

DISEASE SYMPTOMS

The fungus can infect and produce lesions on most above-ground parts of the rice plant, including the leaves, stems, nodes, panicles, and grain. Leaf blast and neck blast are two major symptoms severely affecting plant growth and grain yield. Lesions formed on rice leaves are typically diamond-shaped, with a gray or white center and a brown or reddish brown border, and are 10–15 mm long and 3–5 mm wide (Fig. 1A). Newly formed lesions may have a white or grey-green center and a darker green border. During epidemics, leaf blast at seedling stages (1 month after sowing) can kill young plants completely (Fig. 1B). Blast in developing panicles can result in the complete loss of all rice seeds by causing premature death of the panicles. Later infections may cause incomplete grain fill and poor milling quality.

CAUSAL ORGANISM, DISEASE DEVELOPMENT, AND CONTROL METHODS

Rice blast is caused by the fungus Magnaporthe grisea (Hebert) Barr (anamorph Pyricularia grisea Sacc). M. grisea also causes disease on many other grass species, including economically important crops, such as barley, wheat, and millet, although individual isolates have limited host range and race specificity. The disease cycle of rice blast involves three distinct phases: penetration, colonization, and sporulation (Fig. 2). The cycle begins when a conidium lands on the leaf surface, germinates, and forms a highly specialized penetration structure known as an appressorium. Turgor pressure that develops within the appressorium physically forces a penetration peg through the plant epidermis. After penetration, infectious hyphae grow intracellularly and intercellularly in rice plants and eventually result in lesion development (Fig. 2). Five to 7 days after infection, the fungus produces abundant quantities of conidia that are dispersed by wind or raindrops. Under favorable moisture and temperature conditions, multiple blast disease cycles occur in one growing season and have devastating effects on a susceptible rice crop.

The rice blast disease may progress through several phases starting with leaf blast and followed by collar, panicle, or node blast. Leaf blast usually is more severe earlier in the growing season but declines as leaves become less susceptible later in the season. Several environmental factors affect the progress of rice blast. Long periods of high humidity and moderate temperatures (63–73°F) are favorable to blast disease development. Conidia are produced and released under high relative humidity. The disease is also favored by excessive nitrogen fertilization, aerobic soils, and drought stress.

Integrated management programs have been applied to control the disease. However, due to the cost and environmental damage of fungicides, the use of resistant cultivars has been the most economical and effective method in most rice-growing countries. Many new varieties with high levels of resistance have been developed in the past. Unfortunately, many cultivars lose resistance within 3–5 years after their release because of the high degree of variability in natural populations of M. grisea. Analysis of the population dynamics of the rice blast isolates at the molecular level should provide new insights into their genetic variation and be helpful to prolong the life of newly released resistant cultivars.
The rice blast fungus can be cultured on various media and is amenable to classical and molecular genetic manipulations. Advances in genetic and cell biological studies of this pathogen during the past decade have made the *M. grisea* rice pathosystem an excellent model for investigating fungal–plant interactions.[2] Several efficient protocols and selectable markers are available for fungal transformation.

Both forward and reverse genetic approaches have been used to study fungal pathogenesis in *M. grisea*. Several laboratories have generated or are generating a large number of random insertion mutants by using restriction enzyme-mediated integration (REMI) or *Agrobacterium tumefaciens*-mediated transformation (ATMT) approaches. These collections of transformants have been screened for mutants that are defective in different stages of infection. In the past decade, over 20 *M. grisea* genes necessary for fungal virulence or fitness have been identified by characterizing insertional mutants isolated. Gene disruption and gene replacement approaches have been used successfully to evaluate candidate genes that are likely to be important for fungal pathogenesis. However, the generation of targeted disruption or deletion mutants of specific genes is time-consuming. The transposon-arrayed gene knockout (TAGKO) approach utilizes bacterial transposon mutagenesis to generate cosmid clones with randomly inserted transposons that can be used for sequencing and fungal transformation.[3] Application of other approaches that may be suitable for large-scale analysis of gene functions in *M. grisea* such as RNAi silencing has been discussed by Sweigard and Ebbole.[4]

In recent years, several groups have made significant progress in understanding the molecular mechanisms of appressorial turgor generation and signaling systems regulating infection-related morphogenesis. Major genes

**MOLECULAR BIOLOGY OF THE RICE BLAST FUNGUS**

The rice blast fungus can be cultured on various media and is amenable to classical and molecular genetic manipulations. Advances in genetic and cell biological studies of this pathogen during the past decade have made the *M. grisea* rice pathosystem an excellent model for investigating fungal–plant interactions.[2] Several efficient protocols and selectable markers are available for fungal transformation.

Both forward and reverse genetic approaches have been used to study fungal pathogenesis in *M. grisea*. Several laboratories have generated or are generating a large number of random insertion mutants by using restriction enzyme-mediated integration (REMI) or *Agrobacterium tumefaciens*-mediated transformation (ATMT) approaches. These collections of transformants have been screened for mutants that are defective in different stages of infection. In the past decade, over 20 *M. grisea* genes necessary for fungal virulence or fitness have been identified by characterizing insertional mutants isolated. Gene disruption and gene replacement approaches have been used successfully to evaluate candidate genes that are likely to be important for fungal pathogenesis. However, the generation of targeted disruption or deletion mutants of specific genes is time-consuming. The transposon-arrayed gene knockout (TAGKO) approach utilizes bacterial transposon mutagenesis to generate cosmid clones with randomly inserted transposons that can be used for sequencing and fungal transformation.[3] Application of other approaches that may be suitable for large-scale analysis of gene functions in *M. grisea* such as RNAi silencing has been discussed by Sweigard and Ebbole.[4]

In recent years, several groups have made significant progress in understanding the molecular mechanisms of appressorial turgor generation and signaling systems regulating infection-related morphogenesis. Major genes

![Fig. 2](http://www.dekker.com) The infection cycle of the rice blast fungus. The infection cycle is initiated by attaching three-celled conidia to the rice leaf surface. Germ tubes produced from conidia differentiate into melanized appressoria. *M. grisea* uses the enormous turgor pressure generated in appressoria to penetrate the underlying plant surface. Once inside the plants, infectious hyphae grow in and between plant cells. Eventually, lesions develop and release more conidia to reinitiate the infection cycle.

involved in the melanin biosynthesis, such as BUF1 and RSY1, have been characterized. The melanin layer is essential for lowering the porosity of the appressorial wall and generating hydrostatic turgor pressure. The turgor pressure that develops in melanized appressoria can be as high as 80 bar through the accumulation of glycerol. Mobilization of energy reserves for glycerol synthesis, such as glycogen and lipids, may be regulated by the cAMP signaling pathway, but their utilization is dependent on a mitogen-activated protein (MAP) kinase PMK1. Although the PMK1 pathway regulates appressorium maturation and penetration, the cAMP signaling pathway is involved in surface recognition and initiation of appressorium formation. Both of these signal pathways are critical for infectious hyphal growth after penetration.[2]

Recently, significant progress also has been made in the genetic analysis and isolation of genes controlling host and cultivar specificity. To date, several “avirulence” (AVR) genes have been isolated, including PWL2, AVR-Pita, and AVR-CO39. Interestingly, these genes do not share any conserved domains. AVR-Pita is the only gene whose corresponding resistance gene (Pita) in rice has been cloned and whose direct interaction with Pita has been demonstrated.[5] Sequence analyses revealed that there were frequent spontaneous mutations in the genomic region of the cloned AVR genes. In the case of the AVR-Pita gene, instability is correlated with its location adjacent to a telomere, whereas the unstable PWL2 gene resides in a chromosomal region rich in repetitive DNA. It is still unclear whether the instability of these AVR genes contributes directly to overcoming the effectiveness of the corresponding resistance genes in the host. As additional AVR genes are cloned in M. grisea, knowledge of their chromosomal locations and contexts will be a valuable resource for studying the genetic variability of the pathogen and its relationship with the durability of host resistance genes in rice.

**GENOMICS STUDIES**

*M. grisea* has seven chromosomes and an estimated genome size of ~40 Mb. A high-density genetic map consisting of 203 markers spanning approximately 900 cM was constructed by integrating markers from several laboratories.[6] Small syntenic regions containing highly conserved genes have been identified in *M. grisea* and *Neurospora crassa*. A physical map consisting of BAC contigs assembled by fingerprinting analysis has been constructed for all seven chromosomes and integrated with the genetic map of *M. grisea*. MagnaportheDB is a federated database with the BAC end sequences and the physical and genetic map data.[8]

Random clones from different *M. grisea* cDNA libraries have been sequenced as expressed sequence tags (ESTs) in several laboratories. Currently, there are over 28,000 *M. grisea* ESTs in GenBank. The largest *M. grisea* EST dataset was generated in Ebbole’s laboratory at Texas A&M University by sequencing cDNA libraries constructed with RNA isolated from appressoria, conidia, mating cultures, pmk1 mutant germlings, and mycelia grown on minimal, complete, nitrogen-deficient, and rice cell wall media. The EST sequencing approach has also been used to identify *M. grisea* genes expressed in infected rice leaves.

In 2003, the Whitehead Institute/Massachusetts Institute of Technology Center for Genome Research has generated over 6× coverage of the *M. grisea* 70-15 genome by the shotgun approach. Information about sequencing, assembling, and annotation is available to the public at [www-genome.wi.mit.edu/annotation/fungi/magnaporthe](http://www-genome.wi.mit.edu/annotation/fungi/magnaporthe). It is worth noting here that 70-15 is a strain generated by backcrossing three times to Guy11, which is the first hermaphroditic *M. grisea* isolate pathogenic to rice and is widely used in earlier genetic studies. Although 6× sequencing may be not adequate for assembling the whole genome, it has provided much needed sequence information for functional genomic studies. Microarrays of genes predicted from the rice blast genome sequence are under development and will be very useful to generate expression profiles of *M. grisea* genes in different mutants and plant infection stages.

**FUTURE PERSPECTIVES**

Functional genomic studies of *M. grisea* are likely to be the focus for the next few years and will lead to the identification of genes important for different developmental and plant infection stages. When additional genomes of fungal pathogens and model fungal organisms become available, comparative studies will be helpful to discover genes specific for fungal pathogens or specific for different infection mechanisms. With the availability of the rice and rice blast genome sequences, functional genomics of the rice–rice blast interactions will be more and more accessible as a model and will provide fundamental insights into rice blast disease.

**CONCLUSION**

In the last few years, considerable progress has been made towards understanding the molecular mechanism of the pathogenesis of the rice blast fungus. Several important genes controlling key steps in the development and infection have been well characterized. Few major
genome projects have contributed greatly to characterization of rice blast genome by providing numerous ESTs and the whole genome sequence. Fully understanding the function of the identified genes from the genome projects will be a daunting challenge for rice blast scientists. New tools and technologies will play more vital roles for the studies of the rice blast genes and the development of novel strategies to effectively control the disease.

RNA-Mediated Silencing

Karin van Dijk
Heriberto Cerutti
University of Nebraska, Lincoln, Nebraska, U.S.A.

INTRODUCTION

RNA-mediated silencing involves various epigenetic mechanisms—apparently triggered by double-stranded RNA (dsRNA)—that result in suppression of gene expression. These mechanisms can lead to the degradation of homologous RNAs, translational repression, heterochromatin formation, and DNA methylation. Epigenetic phenomena induced by dsRNA have been observed in many eukaryotes and they may have evolved as defense responses against transposable elements and viruses. Recently, it has become apparent that the basic machinery required for these processes is also involved in the control of development. Moreover, links between RNA-mediated silencing and DNA and chromatin modifications are also starting to emerge. For more on this, the reader is referred to several recent reviews. This article discusses the basic processes leading to RNA silencing, the putative triggers, some of the key plant proteins involved in these pathways, and some potential applications of RNA silencing.

RNA-SILENCING BY RNA DEGRADATION

Posttranscriptional gene silencing (PTGS), cosuppression and RNA-mediated virus resistance in plants and algae, RNA interference (RNAi) in animals, and quelling in fungi are all examples of RNA-mediated silencing. Although these phenomena may differ in the details, central to them appears to be a molecular machinery that processes long dsRNA into smaller dsRNAs—called small interfering RNAs (siRNAs)—which are then used as guides to target homologous RNA molecules for degradation. In the late 1980s and throughout the 1990s, RNA-mediated silencing processes were observed in many eukaryotes. However, it was not realized until the late 1990s that these seemingly different processes are mechanistically related.[1–5] In plants, the initial observation came from research in the Jorgensen lab when an attempt was made to enhance the purple color of petunia flowers by overexpressing chalcone synthase.[4,5] Instead, the reverse happened. The expression of both the transgene and the native gene were diminished, and many flowers lost their pigment. This phenomenon was named cosuppression, and was later found to occur at the posttranscriptional level, hence the name posttranscriptional gene silencing. In the fungus Neurospora crassa, a similar phenomenon was observed, named quelling. Around the same time, researchers working on the nematode Caenorhabditis elegans found that they could successfully interfere with gene expression by injecting antisense RNA. However, to their surprise, injections with sense RNA could also suppress gene expression. We now know that the gene silencing observed in these cases was triggered by the presence of dsRNA, a contaminant produced during the preparation of sense or antisense RNA.[5] This strategy of using dsRNA to silence a target gene is called RNA interference. Researchers have for many years used yet another RNA-mediated silencing process—antisense technology—to interfere with specific gene expression. To achieve this, transgenic organisms are engineered to produce RNA complementary to the target transcript. Although the precise mechanism by which antisense RNA works remains elusive, in at least some cases dsRNA is likely involved as an intermediate.[3]

THE BASIC RNA-MEDIATED SILENCING MACHINERY

The combination of genetic and biochemical evidence from different organisms is starting to reveal the molecular machinery involved in the dsRNA-induced degradation of cellular RNAs. This process can be divided into an initiation and an effector step (Fig. 1).[1,2] In the initiation step, the ATP-dependent dsRNA nuclease DICER (Table 1), initially described in Drosophila melanogaster, chops the dsRNA molecule into siRNAs of about 21–23 nucleotides. In the effector step, the siRNAs are transferred to an enzyme complex—the RNA-induced silencing complex (RISC)—which has an endonuclease activity distinct from DICER. RISC is proposed to unwind the double-stranded siRNAs, and use the antisense strand to identify complementary messenger RNAs (mRNAs). Target mRNAs are then cleaved across from the center of the siRNA-mRNA hybrid and further degraded (Fig. 1). In some eukaryotes, an amplification step appears to be required for efficient silencing (see following discussion).
Moreover, there is also spreading of silencing throughout the whole organism. The exact mechanism is unclear, but in plants it involves a sequence-specific signal that travels between cells as well as through the phloem.\[6\]

**TRIGGERS OF RNA-MEDIATED SILENCING**

Direct delivery of dsRNA (injected, fed, or the result of transcription from inverted repeat transgenes) can induce silencing in a variety of organisms, including plants. One of the fascinating aspects of RNAi, which is particularly noticeable in *C. elegans*, is that minute amounts of dsRNA can trigger degradation of a vast amount of mRNA. Recent studies suggest that the initial dsRNA trigger needs to be amplified to effectively silence target genes.\[7\]

In this model, primary siRNAs are used as primers by an RNA-directed RNA polymerase (RdRP) to synthesize more dsRNA, using the target mRNA as a template (Fig. 1). DICER then cleaves the dsRNA to produce enough siRNAs to effectively target even abundant RNAs for degradation.

With sense and antisense transgenes, a major question is how dsRNA is produced. One model proposes that an
RdRP synthesizes dsRNA from aberrant RNA\cite{1,3} (Fig. 1). What makes an RNA molecule aberrant is not known, but it may involve the production of prematurely terminated, nonpolyadenylated or misprocessed RNAs. Because these transcripts are most likely present in the nucleus, the synthesis of dsRNA by an RdRP is proposed to occur in the nucleus.\cite{1} In support of this model, Arabidopsis mutants in an RdRP, SDE1/SGS2 (Table 1), are defective in the PTGS of sense transgenes. In contrast, silencing induced by viruses, expressing their own RdRP, is not affected in this mutant background.\cite{3}

### MicroRNAs, ANOTHER SMALL RNA SPECIES PRODUCED BY DICER

Additional layers of complexity are emerging as more is discovered about RNA-mediated silencing pathways. For example, DICER can produce another species of small RNAs called microRNAs (miRNAs). MicroRNAs are processed from endogenous precursor RNAs consisting of double-stranded hairpin structures that have regions of imperfect complementarity.\cite{8} MicroRNAs were first identified in C. elegans as products of the genes let-7 and lin-4. These miRNAs are involved in regulating developmental timing by binding to the 3' untranslated regions and preventing translation of their target mRNAs. Thus, in this case, miRNAs induce translational repression rather than mRNA degradation.

Recently, a combined effort has resulted in the isolation of many miRNAs in both animals and plants. The regulatory targets of most of these are unknown, but what has become clear is that the distinction between miRNA and siRNA has become blurred.\cite{11} For instance, one of the Arabidopsis miRNAs has perfect complementarity with the transcripts of a group of transcription factors, and it has been implicated in controlling their expression through degradation of the mRNA.\cite{1,8} Intriguingly, many plant miRNAs have a higher level of complementarity with their potential targets than animal miRNAs,\cite{8} and they may function by regulating transcript stability rather than translation. Moreover, in plants, many predicted targets function as developmental regulators, suggesting that miRNAs might play a role in coordinating growth and development.

### RNA-MEDIATED SILENCING AND CHROMATIN/DNA MODIFICATIONS

In addition to effects at the posttranscriptional level, it is becoming apparent that RNA can direct DNA methylation and chromatin modifications. In several plant species dsRNA can target the methylation of homologous DNA. This RNA-directed DNA methylation (RdDM) was initially observed in viroid-infected plants, and has now been shown to also occur in plants expressing inverted repeat constructs or infected with replicating viruses containing sequences homologous to genomic DNA.\cite{9} When the RdDM occurs in promoter sequences, the target genes are silenced at the transcriptional level, i.e., no RNA is produced. Promoter-directed dsRNA is also processed into siRNAs, but it is not yet clear whether these are required to induce DNA methylation.\cite{1,9}

In plants, many posttranscriptionally silenced transgenes are also methylated, but in this case, methylation occurs within the coding regions. Interestingly, two Arabidopsis mutants, met1 and ddm1 (Table 1), initially isolated in a screen for reduced methylation of the genome, are also defective in their ability to post-transcriptionally silence transgenes.\cite{10} The relevance of this methylation is not clear, but it might be involved in the initiation or maintenance of silencing by affecting the production of aberrant RNA. In addition, RNA has been implicated in heterochromatin formation and maintenance in other organisms.\cite{11} For instance, in Schizosaccharomyces pombe, mutants defective in components of the RNAi pathway show reactivation of transgenes integrated in the centromeric (heterochromatic) regions. This correlates with the loss of histone H3 methylation, which is commonly associated with a repressive chromatin

structure. Thus, RNA-mediated processes may also play a role in chromosomal organization and transcriptional control.

APPLICATIONS OF RNA-MEDIATED SILENCING IN PLANTS

RNA silencing has become an important tool in molecular biology and has the potential to revolutionize functional genomics, because it is an effective way to knock down the expression of any gene. Moreover, since RNA-mediated silencing does not require complete sequence identity between the dsRNA trigger and a target gene, it is even possible to silence the expression of gene families. There are also clear applications of this technology to agriculture. For instance, an RNA-silencing strategy can be used to suppress undesirable traits in plants. As an example, tomatoes that have reduced levels of polygalacturonase (a protein involved in fruit ripening) have been produced by antisense technology. The resulting tomatoes stay firm while ripening on the tomato vine. In the past, the success rate of this technology was somewhat unpredictable. However, a greater understanding of the mechanisms involved in RNA silencing has allowed the design of better constructs. Effective silencing of a particular gene can now be accomplished with inverted repeat transgenes that produce hairpin RNAs (hpRNA) (Fig. 1). One success story, using hpRNA, is the production of cotton seeds with altered fatty acid content due to downregulation of expression of a fatty acid desaturase.

Root Membrane Activities Relevant to Plant-Soil Interactions

Zeno Varanini
University of Udine, Udine, Italy

INTRODUCTION

The plasma membrane of root cells plays a fundamental role in the complex interactions that occur at the soil-root interface, contributing to the transport of solutes into the cell and thus changing the composition of the rhizosphere. Clearly, the biochemical mechanisms regulating the plant-soil interaction must respond and adapt to the conditions both within the root cell and at the rhizosphere; the plant must therefore possess sensing mechanisms that can efficiently modulate transport and enzyme activities at the plasma membrane. There are several classes of membrane-bound proteins, the most important of which in the soil-plant relationship are proton pumps, carriers, channel proteins, and reductases.

PROTON PUMPS

The plasma membrane H\(^+\)-ATPase (pmH\(^+\)-ATPase) is an electrogenic enzyme, exploiting the energy released upon the hydrolysis of ATP to transport protons from the cytoplasm into the apoplast. This enzyme can catalyze the extrusion of over \(10^2\) H\(^+\) ions per second: It is also extremely abundant, forming approximately 1% of the overall amount of proteins at the plasma membrane. Moreover, these levels can increase remarkably under certain conditions (discussed later), in particular in the layers of cells at the soil-plant interface (i.e., the epidermal and root hair cells).

The plant pmH\(^+\)-ATPase is formed by a single polypeptide approximately 100 kDa in size. Its putative topology suggests that the enzyme possesses ten transmembrane regions and four cytoplasmic domains,\(^\text{[1]}\) the latter including the carboxy-terminal region (Ct), an important domain from a posttranslational viewpoint. The Ct has in fact been observed to have auto-inhibitory properties; its effect can however be cancelled when, once phosphorilized, it becomes the binding site for proteins of the 14-3-3 family.

Plant pmH\(^+\)-ATPase is encoded by a multigene family; it is not yet clear if the various isoforms function under specific environmental conditions or are expressed in specific types of cells, tissues, or organs.\(^\text{[1]}\)

The pmH\(^+\)-ATPase plays a fundamental role in the soil-plant relationship, supplying energy for nutrient transport and acidifying the rhizosphere in order to facilitate the roots’ acquisition of certain mineral nutrients; it is also involved in the plant’s response to abiotic stress and signals from the rhizosphere.

Energization of Nutrient Transport

The activity of the pmH\(^+\)-ATPase creates a gradient of pH (more acidic outside the cell) and potential (more negative inside the cell) across the plasma membrane, which is then exploited for nutrient transport by means of carriers or channels (Fig. 1). Cations are attracted to the cell by the membrane potential and could simply enter into the cell through protein channels; anions, on the other hand, require carriers (symporters). This type of transport is an active process, and the energy is supplied by the accompanying inflow of protons. The activity of pmH\(^+\)-ATPase seems to be modulated according to the plants’ nutritional needs. In the case of nitrate, the enhanced uptake brought about by the roots’ exposure to this nutrient (induction) is accompanied by higher levels and thus activity of the pmH\(^+\)-ATPase, presumably to meet the greater demand for proton-driving force.\(^\text{[2]}\) Recent investigations also reveal that treatment with nitrate induces a differential expression of the various forms of the enzyme, thus suggesting that certain members of the pmH\(^+\)-ATPase multigene family may respond specifically to nutrient uptake.\(^\text{[3]}\)

Nutrient Acquisition by Rhizosphere Acidification

By extruding protons into the apoplast, the root pmH\(^+\)-ATPase acidifies the rhizosphere, with major consequences: The lower pH stimulates the release of cations from the exchange sites on the cell wall and the soil colloids, which then pass into the soil solution and reach the binding sites of the transporters on the outer surface of the plasma membrane. The level of rhizosphere acidification brought about by the proton pump can be modulated by processes of secondary transport, and in particular by the ratio of cations and anions taken up by
the root cells. When nitrogen, for example, is taken up as ammonium, rhizosphere acidification increases; the opposite occurs when it is taken up as nitrate.

The acidifying action exerted by the pmH⁺-ATPase has important consequences on the solubilization of essential nutrients characterized by low availability. A well-investigated case is that of iron. This element is mostly present in the soil as ferric ion (Fe³⁺), which is extremely insoluble at neutral or alkaline pH values. Dicots and nongraminaceous monocots (Strategy I plants) can, however, respond to Fe-deficiency by acidifying the rhizosphere—the extent of the process depending on the species—and thus solubilizing and rendering available Fe³⁺. Plant species endowed with a greater ability to acidify can increase root pmH⁺-ATPase activity under conditions of Fe deficiency.¹ Higher levels of the enzyme are present at the plasma membrane, in particular in the rhizoderma and in the root hairs of the subapical root sections.⁵

Response to Abiotic Stress and Signals from the Rhizosphere

The activity of pmH⁺-ATPase can also change when anomalous conditions are encountered at the rhizosphere. Salt stress is a common case: Under these conditions, enhanced proton extrusion may help energize the Na⁺/H⁺
antiporter systems operating at the plasma membrane. Salt stress has been reported to induce pmH+-ATPase gene expression in specific tissues; in tomato plants, the response was ascribed to a single, specific isoform.[6]

Recent studies moreover suggest that under conditions of osmotic shock, there may also be a posttranslational regulation of the enzyme: The interaction with 14-3-3 proteins would appear to increase the H+/ATP coupling ratio.[7] Enhanced enzyme activity has also been observed in the roots of plants growing in acidic environments: Root pmH+-ATPase would therefore also play a fundamental role in preserving cytoplasm pH homeostasis.[8]

Finally, pmH+-ATPase activity also appears to be modulated by other factors present at the rhizosphere, such as humified organic matter. Low-molecular-weight fractions (<3500) in particular can stimulate the activity of pmH+-ATPase with positive effects on ion uptake rates and the ability to acquire iron and other metal micronutrients.[9]

CARRIERS

These membrane proteins can move solutes either up or down electrochemical gradients at a rate of $10^2$–$10^4$ molecules per second. There are three different types of carriers: symporters, antiporters, and uniporers. Whereas the latter moves substances down a concentration gradient, symporters and antiporters can transport a compound against its concentration gradient by contemporaneously transporting a second substance (usually H+) down its electric and/or chemical gradient. Symporters in particular play an important role in the root-soil interaction, as their transport activity of oxoanionic and cationic macronutrients helps modify rhizosphere pH.

Carrier proteins (symporters) have a molecular mass of approximately 50–60 kDa. Their structure includes 12 membrane-spanning regions and in some cases, motifs on their cytoplasmic domains suggesting a posttranslational regulation of their activity via phosphorylation and dephosphorylation. Although no evidence has been found that such regulation may occur in vivo, it has been clarified that the expression of symporter-encoding genes is regulated by nutrient availability at the rhizosphere.[10,11] The modulation of gene expression depends on the nutrient: Nitrate, for example, is taken up from the soil through low- and high-affinity transport systems encoded by NRT1 and NRT2 genes. Some of these transporters are constitutively expressed, whereas others (NRT2.1) are nitrate-inducible and are subjected to negative feedback regulation by the products of nitrate assimilation. On the other hand, the genes encoding high-affinity transporters for phosphate (PT1, PT2) and sulphate (SHST1, SHST2) are derepressed when plants are deprived of the nutrient. Potassium and ammonium are also taken up by symporters when present at the rhizosphere at low concentrations (in a µM range). The carriers are encoded by such genes as HKT1 (Na+/K+ symporter), KUP (H+/K+ symporter), and AMT1 (H+/NH4+ symporter), which are upregulated under conditions of potassium and ammonium deficiency, respectively. Positively-charged micronutrients are transported into the cell via uniport carriers. An example is IRT1, the expression of which is induced in the roots of Fe-deficient plants.[5] The gene encodes a nonspecific Fe uniport carrier that is also capable of transporting other bivalent cations into the cell, including Cd.

CHANNEL PROTEINS

Channels are membrane-spanning proteins that contribute to the diffusion of water and ions down energetically-favorable gradients. Electric or chemical signals control the opening and closing of these proteins; when open, inorganic and organic ions and water molecules pass through them at very high rates ($10^6$ to $10^7$ molecules per second). Channel proteins are involved in several physiological processes: mineral nutrition; cell osmoregulation, by allowing great ion fluxes across the plasma membrane over short periods of time; signalling, by amplifying and propagating electric signals or transporting secondary messengers such as Ca2+; and the control of membrane potential. The most important channels for the root-rhizosphere interaction are those allowing the flow of potassium and water across the plasma membrane and the efflux of organic and inorganic anions from the root cells.

Various types of channel proteins for the influx and efflux of potassium have been identified at the root cell plasma membrane,[12] but it has only been possible to ascribe a physiological role to AKT1, a protein that surprisingly displays both high- and low-affinity kinetics for this nutrient. The channel proteins involved in the efflux of anions (carboxylates and phytosiderophores) are key factors in the response to nutrient deficiencies and in the resistance to aluminum toxicity;[13] in the latter case, it has been suggested that aluminum itself may be the signal triggering the opening of the channels.

As regards water transport, channel proteins called aquaporins (encoded by PIPs) have been found to be involved in this process. When open, they facilitate the passive movement of water molecules down a water potential gradient. The activity of at least some aquaporins appears to be regulated by processes of phosphorylation and dephosphorylation.

Up to now, 30 genes have been found in Arabidopsis for aquaporin homologues. Some of these genes are constitutively expressed, whereas others are known to be temporally and spatially regulated during the plant’s development and in response to stress. Aquaporins are very abundant proteins, and appear to be involved not only in cytosol osmoregulation, but also in the bulk flow of water.
REDUCTASES

Various redox activities are present at the plasma membrane that can transport electrons from cytoplasmic donors (e.g., NADH and NADPH) to oxidized acceptors in contact with the outer surface of the membrane. Among these enzymes, there is the turboreductase, induced in the rhizodermal cells of dicots and nongraminaceous monocots under conditions of Fe-deficiency. Its physiological function is to reduce Fe(III)-chelates present at the rhizosphere, thus allowing the transport of Fe²⁺ into the cell by the IRT proteins (discussed earlier). Recently, a ferric chelate reductase (FRO2) has been cloned: It belongs to the superfamily of flavocytochromes, a class of proteins that mediate the transport of electrons across the membrane, and appears to be strongly induced in Fe-deficient plants. The roles and electron acceptors of the other reductases that are constitutively expressed in the roots of all plant species and are distributed along the entire root axis are still unknown. Since they produce reactive forms of oxygen, they may be involved in the metabolism of cell wall production and in pathogen control. Other authors, highlighting the ability to reduce nitrate, have instead suggested they may also act as sensors in the regulation of nitrate uptake and assimilation.

CONCLUSION

Biochemical and molecular analyses have clarified many aspects of the structure and regulation of plasma membrane activities modulating the root-soil relationship. However, much remains to be learned, and not only with regard to those systems that have been less investigated (i.e., channel proteins and reductases), but also the sensing mechanisms involved in the perception of the environmental conditions. There are also other objectives in the research on proton pumps and nutrient-transporting carriers: to understand the specific role of each isoform and shed more light on the aspects relative to posttranslational regulation. It would be interesting to assess which are the major systems involved in the root-soil relationship in field conditions. This could be a useful parameter in selecting or obtaining genotypes that are more efficient in their interaction with the soil (e.g., greater ability to recuperate nutrients, greater adaptability to adverse conditions, etc.).

REFERENCES

INTRODUCTION

Belowground plant parts constitute a major portion (often >50%) of the biomass and primary plant production available to herbivores. Therefore, it is not surprising that many species of insects have taken advantage of this resource. Root feeding is used here to refer to consumption of all belowground plant parts, including roots, rhizomes, and other storage organs. Root-feeding insects can influence plant diversity, plant succession, competitive interactions among plant species, the susceptibility of plants to other herbivores and plant diseases, and crop yield. This article discusses adaptations insects possess to live in the soil environment, examines some of the diverse species of insects that feed on plant roots, and discusses the effects of root feeding on host plants with emphasis on corn rootworms.

ADAPTATIONS TO THE SOIL ENVIRONMENT

Organisms that spend at least some part of their life cycle underground are referred to in this article as edaphic organisms. Edaphic species that live on the soil surface or in the litter are referred to as epedaphic organisms, whereas those that inhabit mineral strata beneath the litter layer are referred to as euedaphic organisms. Distantly related species that have come to share similar soil habitats may have followed parallel or convergent evolutionary paths, and may appear similar in form. A major factor limiting insect occupation of the soil has been the ability of these organisms to move. Most insects are not small enough to travel through interconnected pore spaces and must therefore either tunnel through the soil (by pushing soil particles aside and squeezing through) or excavate it (removing the soil in front and moving it behind them). Burrowing insects are generally round in cross section, but may otherwise vary in shape. Insects that tunnel often have very small or no legs, and may be of two body forms. Wireworms (the larval stage of click beetles; Coleoptera: Elateridae) are often smooth, slender, and hard-bodied; using a serpentine motion, they are able to force their wiry-like bodies through the soil. In contrast, corn rootworm larvae (Coleoptera: Chrysomelidae) are soft-bodied and can use peristaltic movements to pass through the soil. Soil insects that move by excavating the soil are often armored and thick-bodied, and may display modified forelegs for digging, such as in mole crickets (Orthoptera: Gryllotalpidae) or nymphal periodical cicadas (Homoptera: Cicadidae). Wings are generally reduced in adult insects that spend much of their lives in the soil, and compound eyes are often reduced or absent. In contrast, tactile sense organs are generally well developed in euedaphic insects, and many of these insects are sensitive to carbon dioxide, which is often used to locate plant roots. In some species, such as the Japanese beetle, Popillia japonica (Coleoptera: Scarabaeidae), grubs can move vertically through the soil profile as seasonal soil temperatures change, and thus remain active and able to feed on plant roots.

DIVERSITY OF INSECTS THAT FEED ON PLANT ROOTS

Insects that feed on roots are represented in most of the larger insect orders. The burrower bug, Cyrtomenus bergi (Heteroptera: Cydnidae), is a serious pest of cassava, a very important crop in low-income, food-deficit countries. All five nymphal stages and the adult stage of these small oval bugs live in the soil. They damage this root crop by directly feeding on the roots. Fungal pathogens can enter these wounds, reducing both root yield and quality. Some root-feeding scale insects in the genus Margarodes (Homoptera: Coccidae) are given the common name of ground pearls, for the pearl-like appearance of the wax cysts of females. Ground pearls often cause injury to vine crops, turf, and sugarcane, and are very difficult to control because the insects are protected by the cysts. Encysted insects are also able to resist extreme temperatures and low moisture levels, and adult females have been able to prolong emergence for several years. Root-feeding insects may also facilitate the transmission of plant pathogens. For example, root feeding by larvae of the striped cucumber beetle, Acalymma vittatum (Coleoptera: Chrysomelidae), was found to increase the incidence and severity of Fusarium wilt of muskmelon. Other root feeders have intricate life histories with other insect
species. For example, eggs of the corn root aphid, *Aphis maidiradicis* (Homoptera: Aphididae), pass the winter in nests of ants in the genus *Lasius*. In the spring, when the eggs hatch, the ants carry the nymphs to roots of weeds where the aphids feed. Later, the ants transport the aphids to the roots of maize. All the while, the ants feed on honeydew produced by the aphids.\(^3\)

**CORN ROOTWORM LARVAL FEEDING ON MAIZE**

The western corn rootworm, *Diabrotica virgifera virgifera*, and the northern corn rootworm, *Diabrotica barberi*, are the most serious insect pests of maize in the major maize-producing states of the United States and Canada. Both species have a single generation per year. Adults are present in maize fields from July through frost, and feed on maize foliage, pollen, silks, and developing kernels. Oviposition takes place almost exclusively in maize fields from late-July through mid-September (since the mid-1990s, however, western corn rootworms have also begun to lay eggs outside of maize fields in east-central Illinois and northern Indiana, rendering crop rotation ineffective in the management of this species in those areas). Diapausing eggs spend the fall and winter in the soil until late May or early June when they hatch and the larvae begin to feed on maize roots (larvae can only complete development on maize and a few grassy weeds). Newly eclosed larvae feed primarily on root hairs and the outer tissue of roots, causing little significant injury. As the larvae grow, root tips may be pruned back and larvae may tunnel into larger roots. Growing points at root tips may also be killed; this often leads to fibrous secondary root production. Larval feeding disrupts root system function, reducing the amount of water and nutrients supplied to developing plants, which can in turn reduce grain yield. Larval feeding may also facilitate infection by root and stalk rot fungi, resulting in further damage. Brace roots may also be severely damaged, causing plants to lodge and stalks to gooseneck. Altered leaf orientation can reduce photosynthetic efficiency of the plant; difficulty in mechanically harvesting the lodged maize can result in additional yield losses.\(^7\) In some cases, rootworm injury has slowed plant development, leading to asynchrony between tassels and silks and resulting in a greater percentage of plants with barren ears.\(^8\)

Root-injury ratings have been used to assess larval injury by corn rootworms. Some investigators have estimated that a mean root-injury rating > 2.5 (on a 1-to-6 root-injury rating scale, where 1 = minor injury and 6 = three nodes of roots destroyed) would result in economic loss. Other workers showed that root injury ratings were not consistent predictors of yield. Numerous factors influence the extent of damage and its impact on yield. Number and species of larvae, size of the root system, ability of the maize hybrid to regenerate roots, availability of soil moisture and nutrients, plant population, and weather are all involved in the amount of damage that may occur and the impact this damage may have on yield. If other stress levels are minimal, severe root damage may not result in significant yield losses, particularly if high winds do not cause lodging.\(^7\)

A recent four-year field study using 12 commonly grown maize hybrids and natural infestations of corn rootworms at two locations in Illinois showed that hybrid characteristics and environmental conditions—particularly soil moisture—can strongly affect the level of root injury needed to cause economic damage. During one year of the study when growing conditions were stressful (low soil moisture), economic damage occurred with some hybrids when the average root rating was only 2.5 (on the 1–6 root-injury rating scale). When growing conditions were more favorable, economic damage did not occur with the same hybrids until root-injury ratings were 4.0 or higher.\(^9\) The complex interactive effects that maize genotype, level of rootworm larval injury, and environment have on grain yield suggest that maize hybrids may differ in their ability to tolerate rootworm injury and partition biomass between vegetative and reproductive tissue. That is, injury to the roots can reduce (to varying degrees, depending on hybrid) the allocation of resources toward seed production as more of the plant’s resources are allocated to replace injured roots.\(^10\)

**CONCLUSION**

For corn rootworm management alone, approximately 88% of nonrotated maize hectares (estimated at over a million hectares) in Illinois are treated with a soil insecticide.\(^9\) The introduction of genetically modified crops with activity against root-feeding insects will revolutionize the way these pests are managed. Although these new crops will likely reduce reliance on soil-applied insecticides, effects on non-target organisms and the development of resistant insect populations must be looked out for.

Rubisco Activase

Archie R. Portis

USDA and University of Illinois, Urbana, Illinois, U.S.A.

INTRODUCTION

Rubisco activase is a protein that is required in the higher plants to maintain and regulate the activity of Rubisco, the protein formally known as ribulose 1,5-bisphosphate carboxylase/oxygenase. Rubisco is a very important protein in photosynthesis because it initiates both photosynthetic carbon metabolism via its carboxylase activity and photorespiration via its oxygenase activity.[1] The activity of Rubisco is a major factor limiting photosynthesis and thus the productivity of many of our major crops. The properties of Rubisco activase and the current understanding of the regulation of Rubisco by the activase will be discussed.

WHAT IS KNOWN ABOUT THE STRUCTURE OF THE ACTIVASE?

Rubisco activase is a member of the very large and diverse AAA+ protein family that contains related sequence domains forming a common structural motif, which binds ATP. AAA+ proteins use the energy provided by ATP hydrolysis to perform a wide variety of functions.[2] For example, AAA+ proteins are involved in proteolysis, DNA synthesis, membrane fusion, and microtubule severing and trafficking. Thus they constitute a novel type of molecular chaperone, which acts to manipulate other molecular or macromolecular structures. In performing these functions, large multimeric complexes are often assembled, which may contain other proteins. The AAA+ proteins in these complexes contain one or more copies of the AAA+ motif and typically form ring structures consisting of six or seven AAA+ proteins.

Rubisco activase is highly self-associating and oligomerization of the protein is closely linked to its ATP hydrolysis activity.[3] However, the exact structure of activase has not yet been determined and the types of macromolecular structures it can form remain unclear. Based on a wide variety of evidence, a working model for its activity has been proposed (Fig. 1). In this model the activase forms a ring around the Rubisco holoenzyme, which consists of eight large and small subunits that form eight active sites. ATP hydrolysis is proposed to cause conformational changes in the ring, and thereby in Rubisco.

WHY DO PLANTS NEED ACTIVASE AND HOW DOES IT WORK?

The active site of Rubisco is capable of binding a wide variety of sugar phosphates (ligands) as well as its substrate, ribulose 1,5-bisphosphate (RuBP).[1,3] In addition, the amine group of a lysine residue in the active site must be carbamylated by addition of an “activating” CO₂ molecule, in order for carboxylation or oxygenation of RuBP to occur. While only minor changes in the conformation of the enzyme occur with carbamylation, much more dramatic and similar changes occur with the binding of certain ligands to both the carbamylated and uncarbamylated forms of the enzyme.[4] The binding of these ligands causes conformational changes that close off the active site so that the ligand is completely surrounded. This results in the ligand being bound very tightly, and its dissociation from the active site is very slow. Catalysis is possible only when RuBP binds to a carbamylated site. Physiologically, two of the more important ligands involved in inhibiting the activity of Rubisco in this manner are RuBP, which also binds to uncarbamylated active sites, and 2-carboxyarabinitol 1-phosphate, which prefers carbamylated sites.[3] Either directly or indirectly, Rubisco activase appears to reverse the conformational changes that sequester these ligands, allowing them to leave the active site more quickly. The activase was named for its ability to rapidly restore activity to Rubisco that has RuBP bound to uncarbamylated sites. Thus, depending on its ATPase activity, the activase can maintain and regulate the activity of Rubisco at a level appropriate for photosynthesis when it is limited by other factors, such as when light intensity is limiting.

Reductions in Rubisco activity can also occur during catalysis.[5] The reaction sequence is quite complex and various “mistakes” have been shown to occur.[1] In several cases it has been shown that an aberrant sugar phosphate product remains tightly bound so that in the absence of Rubisco activase activity, catalytic activity decreases to a low level.
The activity of the activase also plays another important role in photosynthesis by promoting a higher carbamylation state for Rubisco (and thus increased catalytic activity) than would otherwise be possible at atmospheric levels of CO₂. Indeed, activase was discovered by characterizing a mutant of *Arabidopsis* that required high CO₂ for growth. Studies of the isolated enzyme showed that less than half-maximal carbamylation is possible with the physiological conditions in the chloroplasts where Rubisco is located. While ligand binding can either increase or decrease carbamylation, the bound ligands also prohibit the needed substrate, RuBP, from binding. A kinetic way out of this apparent conundrum was provided by modeling the effects of activase on ligand binding. The modeling shows that a steady-state level of nearly maximal carbamylation can result from a difference in the ability of activase to promote the release of RuBP from the carbamylated and uncarbamylated forms of the active site.

In addition to playing a critical role in the regulation of Rubisco in response to changes in light intensity and source-sink balance, recent studies indicate that the activase may play an important role in the response of photosynthesis to high-temperature stress. A decrease in the activation state of Rubisco contributes to the reduced rates of photosynthesis at high temperatures. Current evidence indicates that as temperature increases, there is an increased rate of Rubisco inactivation and a reduced activity of the activase, which is quite temperature-labile compared to other photosynthetic enzymes.

**HOW IS THE ACTIVASE (AND THUS RUBISCO ACTIVITY) REGULATED?**

In most plants surveyed to date, Rubisco activase comprises two isoforms of 41–43 kDa and 45–46 kDa. These usually arise from one or more nuclear genes via alternative splicing, and after import and processing of the intermediate forms containing a chloroplast transit peptide. The larger isoform contains an additional domain at the carboxy-terminus, including two cysteine residues. These cysteines provide the ability to regulate the ATPase and Rubisco activation activities via light-induced redox changes mediated by thioredoxin-f, as shown by studies of Rubisco activation in transgenic *Arabidopsis* plants expressing mutant forms of the activase. Oxidation/reduction of these cysteines alters the response of the ATP hydrolysis and Rubisco activation activities to the ATP/ADP ratio in the chloroplast, such that the activase consumes little ATP in the dark when Rubisco activity is not needed. Regulation of the activase via the ATP/ADP ratio in the chloroplast also appears to provide a means to regulate Rubisco activity in response to source-sink changes that alter the demand for the products of photosynthesis. However, several species appear to contain only the smaller isoform, yet the regulation of Rubisco appears to be quite similar to that in the species with both isoforms. Obviously, understanding the regulation of Rubisco in these plants will require more study.

**CONCLUSION**

Rubisco activase is representative of a rapidly growing class of chaperone-like proteins that are specifically tailored to cover a diverse range of cellular activities requiring alterations of molecular or macromolecular structure. The target of the activase is Rubisco, for which the activase overcomes various problems Rubisco has in carrying out its functions and provides a means to regulate Rubisco activity in response to various environmental factors. Whether or not photosynthesis can be improved by modifying the regulation of Rubisco via the activase is
currently being investigated. Meanwhile, there clearly is considerable potential for modifying Rubisco or expressing foreign forms of the enzyme in order to improve crop productivity. In order to achieve this goal, proper interaction between Rubisco and the activase will have to be maintained.

Secondary Metabolites as Phytomedicines

Donald P. Briskin
University of Illinois, Urbana, Illinois, U.S.A.

INTRODUCTION

Throughout history, plants have provided a rich source for the development of human medicines. Given rising demand for phytomedicines, production of medicinal plants as alternative crops could provide important new opportunities in agriculture. This article briefly discusses the fundamental aspects of phytomedicinal chemical production by plant cells and surveys eight medicinal plants that have received considerable attention over the past decade.

HISTORY

From the earliest times of human history to the beginning of the 20th century, plant medicinal products represented a significant component in conventional medicine, but their use declined with the development of modern pharmaceuticals (e.g., aspirin and quinine) containing pure chemical compounds. Many of these modern pharmaceuticals may have been based on active chemicals isolated from plants, and the development of synthetic or semisynthetic derivatives led to drugs with a consistent dose and even higher levels of potency. Nevertheless, the enhanced dose of one or a few active chemicals in these modern pharmaceuticals frequently resulted in problematic side effects, and these modern pure drugs were often expensive.[1]

Over the past decade there has been a strong resurgence in interest in and use of medicinal plants and phytomedicines, especially in North America. Recent surveys of phytomedicinal use by the American public have shown an increase from about 3% of the population in 1991 to over 37% in 1998.[2,3] By 2002, the North American market for plant medicinal products had reached about $4.1 billion/year.[3] No doubt a major factor contributing to this great increase in phytomedicinal use in the United States has been the passage of federal legislation in 1994—the Dietary Supplement Health and Education Act (DSHEA)—that facilitated the production and marketing of phytomedicinal products.[1,2]

PLANT SECONDARY METABOLITES AND PHYTOMEDICINES

The pharmacological actions of plant materials typically result from combinations of secondary metabolites that are present in the plant. The medicinal actions of plants are frequently unique to particular plant species; the combinations of secondary metabolites in a particular plant species or family are often taxonomically distinct.[4,5] This is in contrast to primary metabolic products—such as carbohydrates, lipids, proteins, and nucleic acids—that are common to all plant species, and are involved in the fundamental biochemical processes of building and maintaining plant cells.[5]

Although secondary products can have a variety of functions in plants, it is likely that their ecological roles may have some bearing on potential medicinal effects for humans. For example, secondary products involved in plant defense through cytotoxicity toward microbial pathogens could prove useful as an antimicrobial phytomedicine, if not too toxic to humans. Likewise, secondary products involved in defense against herbivores through neurotoxin activity could have beneficial effects in humans (i.e., as antidepressants, sedatives, muscle relaxants or anesthetics) through their action on the central nervous system. In order to fulfill functions in promoting the ecological survival of plants, molecular structures of secondary products have evolved to interact with molecular targets affecting the cells, tissues, and physiological functions in other competing microorganisms, plants, and animals.[4,5] In this respect, some plant secondary products may exert their action by resembling endogenous metabolites, ligands, hormones, signal transduction molecules, or neurotransmitters, and thus have beneficial medicinal effects on humans due to similarities in their potential target sites.[5]

BENEFITS OF CHEMICAL SYNERGISMS

In contrast to synthetic pharmaceuticals based on single chemicals, many phytomedicinals exert their beneficial effects through the action of several chemical compounds acting additively or synergistically at single or multiple
target sites associated with a physiological process. As pointed out by Tyler,\(^1\) this synergistic or additive pharmacologic effect can promote pharmacological effectiveness without the problematic side effects associated with the predominance of a single xenobiotic compound in the body. In this respect, Kaufman et al.\(^5\) extensively document how synergistic interactions underlie the effectiveness of a number of phytomedicines. This theme of multiple chemicals acting in an additive or synergistic manner likely has its origin in the functional role of secondary products in promoting plant survival.\(^4,5\) For example, in the role of secondary products as defense chemicals, a mixture of chemicals having additive or synergistic effects at multiple target sites would not only ensure effectiveness against a wide range of herbivores or pathogens, but would also decrease the chances of these organisms developing resistance or adaptive responses.\(^4,5\)

**MEDICINAL USES AND ACTIVE PHYTOMEDICINAL CHEMICALS OF SEVERAL FREQUENTLY USED MEDICINAL PLANTS**

Whereas there are thousands of medicinal plants utilized in Western and non-Western medical approaches, a relatively small number have been the subject of considerable interest in the United States over the past decade.\(^1,2\) As shown in Table 1, eight medicinal plants have tended to dominate the total market for U.S. sales of medicinal plant products since 1998.\(^2,3,6\) In general, the medicinal plants shown in Table 1 have remained within the top 10–15 plants dominating medicinal plant sales, although their percentage of the market has varied from year to year.\(^6\)

Due to the extensive nature of their use in both North America and Europe, these eight medicinal plants have been the subject of considerable study with respect to their

biochemical characteristics and pharmacological properties. For each of these plants, Table 2 summarizes their possible medicinal actions, active phytomedicinal chemicals that have been identified, and pharmacological mode of action, if known. Detailed information regarding the phytochemistry, pharmacology, and toxicology of these medicinal plants can be found in works by Schultz et al.\textsuperscript{[7]} and Cupp.\textsuperscript{[8]}

CONCLUSION

Although medicinal plants have had long-standing use throughout human history and are of considerable interest as alternatives to synthetic pharmaceuticals, there is a paucity of basic knowledge and research on their physiology and biochemistry. It is clear that few widely used medicinal plants have received the extensive physiological, biochemical, and genetic characterization applied to food crops or model plant systems such as \textit{Arabidopsis}. Although active chemicals have been identified in many medicinal plants, the pathways for their biosynthesis and the genetic and environmental factors regulating their biochemical production are in many cases unclear.

At present, a major concern over the use of phytomedicines regards the maintenance of consistent medicinal quality in botanical medicines.\textsuperscript{[9]} Whereas the focus has tended to be on quality control in herbal manufacturing practices (good manufacturing practices (GMP)), variation in phytomedicinal content due to environmental effects on secondary plant metabolism in plant material can also represent a significant factor in determining the quality of the plant material entering the botanical medicine production process and the efficacy of the resulting product. The use of molecular and biotechnological approaches to medicinal plants would also have wide application and promise, especially with regard to metabolic engineering of phytomedicinal chemical pathways and the in vitro production of phytomedicinals in large-scale tissue culture systems such as bioreactors.\textsuperscript{[10]}

INTRODUCTION

The relationship between seed dormancy and success of a plant as an agricultural weed is significant. Holm et al. [1] estimated that there are about 250 significant weeds in world agriculture. If the top 40 weeds classified as “serious” are selected by ranking them according to the number of countries in which they are considered “serious” weeds, it can be shown, without exception, that each one of the 40 species has dormancy. If weed seed were forever dormant, or simply nondormant, the complexities of weed management would be greatly reduced. However, weed seeds vary widely with respect to degree, duration, and source of dormancy. The existence of large populations of weed seed with varying degrees and states of dormancy is the basis for the annual weed problem. Dormancy allows a weed seed to avoid germination when conditions are not appropriate to complete its life cycle and prolongs population survival in the form of a soil seed bank.

CHARACTERISTICS OF THE SOIL SEED BANK

All of the viable seed present on the surface and in the soil is usually described as the soil seed bank. The number of seeds in the seed bank is determined by the rate of input in the seed rain, minus the losses resulting from disease, predation, and germination. The seed bank consists of new seeds recently shed by a parent plant, as well as older seeds that have persisted in the soil for several years. All of these seeds will vary in depth of burial and state of dormancy. Only a small proportion of seeds, varying between and among species, germinate when conditions are favorable. It is generally assumed that annual species contribute up to 95% of the seeds in the agricultural seed bank and only 2 to 10% of weed seeds emerge as seedlings each year.

Because most weeds are capable of producing a high number of seeds, especially compared to cultivated species, a few uncontrolled plants can rapidly increase the number of seeds in the soil seed bank. Data collected from plants grown in monoculture showed that wild oat (Avena fatua) produced 372–623 seeds,[2] common lambsquarters (Chenopodium album) produced 75,600–150,400 seeds,[3] and Palmer amaranth (Amaranthus palmeri) produced 200,000 to 600,000 seeds per plant.[4] It should be noted that biotic (inter- and intraspecific competition) and abiotic (climate) factors affect seed production, and most plants in agricultural situations do not often approach these high seed production values.

Large numbers of seeds are dispersed both horizontally and vertically in the soil. Plowing, chiseling, disking, and other forms of tillage are major ways that seeds are moved and covered with soil. After a number of years of soil disturbance, a relatively stable vertical distribution of seeds is reached in the tillage zone. Early estimates of seed numbers in agricultural soils exceeded 100,000 seeds per hectare in the tillage layer. Samples of soil on well-managed farms in Minnesota averaged 16 million seeds per hectare, and as many as 45 million per hectare have been counted.

PERIODICITY AND INTERMITTENT GERMINATION

Most weed species exhibit annual periodicity in germination and emergence restricted to certain times of the year. This behavior was part of the original evidence for annual cycles in the relief and imposition of seed dormancy. Observations on seed germination and seedling emergence from soil samples placed in the greenhouse revealed that there was a typical periodicity, as well as a period of maximum germination for more than 100 weed species.[5] Exhumed seeds of corn spurry (Spergula arvensis) showed clear seasonal changes in dormancy during three successive years of germination tests.[6] Often, seeds are conditionally dormant, i.e., the appropriate conditions for germination are not present; seeds of winter annual species will not germinate in late spring, and spring annual species will not germinate in late fall.

WEED SEEDS AND DEPTH OF BURIAL

Seed germination and emergence of seedlings from various depths below the soil surface depend on the degree of dormancy present and conditions of the immediate
environment. However, dormancy-breaking stimuli are most effectively encountered and germination is rapid when seeds remain at or near the soil surface. There is an overall agreement that the number of seedlings and rate of seedling emergence decrease proportionately with increases in the depths of seed burial. Examination of seeds recovered from 12 cm deep showed that approximately 85% were completely dormant. The results of these investigations also revealed a strong association between seed mass and maximum depth of emergence, with the heaviest seeds emerging from the greatest depths.

PERSISTENCE OF WEED SEEDS IN SOIL

It is quite common for seeds to be dormant when they are fully mature on the parent plant and for dormancy to be lost after they are shed. The term “after-ripening” has frequently been used to denote the interaction between environment and seed over time that leads to a loss of dormancy. The length of the after-ripening period varies between and among species and by seed location on the plant. Most weed species show one or two periods of high percent germination in seed produced during any given year, and the percent germination in subsequent years can be quite low. The mean length of the dormancy period in populations drives turnover in the seed bank. Grime makes a distinction between “transient” (complete turnover in less than one year) and “persistent” seed banks (some seed remains in the bank longer than one year). The term “aging” is sometimes used incorrectly to describe after-ripening. Aging reduces seed viability and seedling vigor.

ENVIRONMENTAL FACTORS THAT AFFECT SEED DORMANCY

Temperature

Temperature is the major environmental factor to cause a change in seed dormancy. Temperatures may break dormancy but also send seeds into dormancy when other environmental conditions are limited. Seeds of summer and winter annual weeds may be conditionally dormant due to temperature influences. Experimentally, the effect of chilling is tested through exposure of imbibed seeds to low temperatures, usually around 0 to 1°C, for a substantial period. Seeds of bur buttercup (Ranunculus testiculatus) germinated only at very cold incubation temperatures, and maximum germination occurred at 5°C. Seeds of winter annual species must be exposed to high fall temperatures. If lack of moisture prevents seeds of obligate winter annuals from germinating in the fall, low winter temperatures may induce dormancy. Consequently, viable seeds that fail to germinate in the fall cannot germinate in spring because they are dormant. Seeds of the winter annual Japanese brome (Bromus japonicus) were forced into dormancy with winter temperatures and would not germinate during the spring and summer, despite favorable germination conditions.

Under natural conditions in the soil, seeds are subjected to fluctuating temperatures. It has been observed that random fluctuations in temperature, in and above a low temperature, are as effective in promoting germination as exposure to constant low temperatures. It has also been found that seeds which remain dormant at constant temperatures may be induced to germinate by a diurnal fluctuation of temperatures. Thompson and Grime investigated the effect of fluctuating temperatures on the germination of 112 species of herbaceous plants. Forty-six of the species examined were found to have their germination stimulated by temperature fluctuations in the light.

Light

Exposure to light breaks dormancy in many weed species, but there may be situations in which light has no effect or even inhibits germination. Baskin and Baskin observed that among 142 species, germination of 107 was promoted by light, 32 were unaffected by the difference in light and dark conditions, and 3 were inhibited by light. Wesson and Wareing concluded that “under natural conditions in the field, the germination of buried seeds following a disturbance of the soil is completely dependent upon exposure of seed to light.” Even a short exposure or “light break” was sufficient to significantly increase the total number of seedlings emerging from soil.

CONCLUSION

Understanding the processes of dormancy loss and germination is essential to the development of good weed management programs. Currently, most management programs aim to control emerged weed populations and affect the quantity of seed returned to the soil, but it should be recognized that almost all agronomic practices also affect weed seed dormancy and germination through manipulation of the soil environment. Because many agricultural weeds exhibit periodicity of emergence, tillage treatments, planting dates, and other cultural practices can be altered to follow peak germination times and
maximize depletion of the seed bank. A natural population of viable weed seeds in the field declined at a rate of approximately 50% per year with frequent cultivation.\[^{15}\]\n
A review of the utilization of specific agronomic practices to manipulate weed seed dormancy and germination requirements for weed management is available from Dyer\[^{16}\] and others.\[^{17,18}\]\n

Seedborne Pathogens

INTRODUCTION

Seedborne pathogens are infectious agents, such as bacteria, fungi, mollicutes, nematodes, viroides, and viruses, that are associated with seeds and which can cause diseases in seeds, seedlings, and plants. These pathogens are capable of causing spots and discoloration in seed coat, change in seed size, loss in seed germination, and reduction in seedling vigor and of producing symptoms often leading to seedling death. Through seeds, such pathogens get transmitted to plants, causing symptoms and ultimately affecting production of seeds in terms of both quality and quantity. Seedborne pathogens can completely or partly replace seeds, such as occurs in ergot, smuts, bunts, and nematode galls.

Some seedborne pathogens can be exclusively seedborne and seed transmitted, while others can be both seedborne and at the same time soilborne or present in collateral hosts. Seedborne pathogens are found in seed lots as contaminations, present on the surface of the seed and/or located in the seed coat, pericarp, endosperm, and embryo. They get transmitted to plants of the next generation systemically, locally, or both locally and systemically.

Many seedborne pathogens are economically important as they are able to cause appreciable losses in crop yield. The losses are enumerated in several large publications that readers should consult because they give comprehensive accounts of different types of seedborne pathogens, mechanisms of seed infection, seed transmission, spread, survival in seeds, and control of diseases caused by such pathogens. Some crop-oriented publications are also of importance. The electronic version of the Crop Protection Compendium (2002) of CAB International provides useful information on a number of aspects of seedborne pathogens that cause diseases in agricultural, horticultural, and industrial crops, medicinal plants, and forest tree species.

IMPORTANCE OF SEEDBORNE PATHOGENS

Seedborne pathogens are important because they affect the planting value of a seed lot and the spread of the disease as seeds get transported from infested areas to noninfested areas. This is also a mechanism by which new races, strains, or pathotypes travel from one region to another region of a country and across international boundaries (Figs. 1–4).

The importance of seedborne pathogens is realized when infected seeds are sown in the field. Depending on seeding rate, even a trace seed infection can bring thousands of infected seeds in a one-hectare area of land, as seen in Table 1. These large numbers of infected seeds, when distributed uniformly in a randomized fashion in the field, increase their role in disease development.

Seedborne pathogens, including some commonly occurring saprophytic organisms, are able to spoil seeds and grains by producing toxins, especially in bad storage conditions. Such spoilage makes the grains unfit for human and animal consumption.

DETECTION OF SEEDBORNE PATHOGENS

Laboratory test methods are available for detecting seedborne pathogens. A recently published book[4] and Seed Health Testing Methods, Annex to Chapter 7 of International Rules for Seed Testing, Edition 2003, published by International Seed Testing Association (ISTA), are essential resources for detecting fungi. Most of the sporulating fungi are detected by incubation methods (Fig. 5). Some fungi, which are located in the embryo, are detected only by the embryo count method.[4]

Bacterial pathogens can be detected by plating of seeds on agar media; liquid assays; growing plants for symptom
development; biochemical, serological, and molecular tests; and using bacteriophages. Viruses are detected by examining dry seeds, germinating seeds, or seedlings raised from seeds, followed by indicator plant test, serology, molecular tests, and electron microscopy.

Most nematodes present in seeds can be extracted using a simple Baermann-funnel technique and by direct inspection of seeds for wheat gall nematode.

**CONTROL OF SEEDBORNE PATHOGENS**

Pathogens found in seeds can be controlled using physical, chemical, and biological means. In general, it is advisable to grow crops by using, as far as possible, pathogen-free seeds, preferably of resistant cultivars, or seeds collected from fields and areas where either specific diseases do not occur or the disease pressure is low.

The choice of control measures depends on the types and nature of pathogens. Those pathogens that are exclusively seedborne are easy to control by appropriate seed treatments. The control, however, is difficult when the pathogens are both seedborne and soilborne or when they are also present in collateral hosts (weeds and hosts other than primary hosts).

As seeds infected by pathogens are often discolored, spotted, and lighter in weight, they can be removed to a great extent by seed-cleaning machines, by soaking in brine solution, by hand (manually), or by winnowing. Clean seeds thus obtained give seedlings of higher vigor and better plant stand (Fig. 6), and the yield from such plants is higher.

CONCLUSION

Seedborne pathogens are one of the major constraints in agriculture as they can affect physical appearance and nutritional value of seeds or grains, spoil grains by producing toxins, reduce germination, cause death of seedlings and plants, act as initial inoculum for disease development in the field, and move with seeds from infested areas to noninfested areas. Therefore, seedborne pathogens must receive due consideration in agriculture across the globe. Seeds must be tested before sowing by internationally accepted seed health test methods. Infected seeds must be removed as far as possible from sowing or should be sown only after proper seed treatments.

Usually, the seeding rate is expressed in kg per hectare, but the number of seeds per gram can be calculated in the laboratory. This will help in calculating number of seeds per hectare.

The above table can be expanded. It will help in knowing the number of seeds that will enter a field, but the rate of transmission of seedborne pathogens will depend on the nature of the pathogen, susceptibility of the host, soil conditions, environmental conditions, cultural practices, etc.

INTRODUCTION

Seed dormancy is most easily observed and measured as the absence of germination in an imbibed, viable seed. Its intrinsic nature is, however, less easily defined physiologically. Almost all seeds go through a dormant phase if only to prevent viviparous germination on the mother plant. Many crop species have been selected for low dormancy to ensure rapid and uniform crop establishment. Residual dormancy, however, causes problems for seed germination testing, volunteers in crops, and low germination in the brewing industry.

Prevention of immediate germination through either dormancy or quiescence is a crucial element in the regeneration strategy of many wild plants. The success of such a strategy depends on quantitative and sometimes qualitative differences in dormancy within seed populations.

Stimulation of germination of dormant seeds frequently occurs as a function of fascinating interactions of environmental or chemical stimuli with the annual dormancy cycle of seeds in the soil. These interactions lead to the periodicity of emergence. Quantifying differences within seed populations with respect to environmental factors is the key to predictive models for the germination and emergence of dormant seeds.

DEFINING DORMANCY

Dormancy is usually defined in the way it is most often measured and observed—negatively:

The failure of a viable seed to germinate given moisture, air and a suitable constant temperature for radicle emergence and seedling growth.\(^1,2\)

Attempts to define dormancy positively include “a seed characteristic, the degree of which defines what conditions should be met to make the seed germinate,”\(^3\) but how is the degree of an unspecified characteristic to be measured?

Seed dormancy is sometimes classified by the phenological stage when dormancy is induced or by the putative mechanism.\(^4\) A distinction of particular value is that between primary (innate) and secondary (induced) dormancy. Primary dormancy develops during seed maturation on the mother plant, while secondary dormancy is induced after shedding.

DEFINING QUIESCENCE

Absence of one or more of the three prerequisites for germination of a nondormant seed (moisture, air, and a suitable temperature) usually reduces metabolism.\(^5\) Nongermination of nondormant seeds can, therefore, arguably be called quiescence, again defined negatively:

The failure of a viable seed to germinate due to shortage of water, poor aeration or an unsuitable temperature for radicle emergence and seedling growth (cf. Ref. 1).

Quiescence is frequently enforced by the environment as in air-dry seeds or in imbibed seeds below the base temperature for the rate of germination of nondormant seed.

Hardseededness, sometimes called physical dormancy,\(^4\) is strictly innate quiescence. Best known in the Leguminosae, hard seeds, which are impermeable to water, occur in several other plant families.\(^1\) Like innate dormancy, impermeability develops during maturation drying on the mother plant and it may increase after shedding in dry environments. Although hard seeds are easily made permeable by mechanical abrasion, some of the greatest longevities of seeds in the soil are achieved by such innately quiescent, hard seeds, which possess no primary dormancy.

MEASURING DORMANCY

Phytochrome is integrally involved in many photomorphological responses in plants, and seed germination is no exception.\(^5\) It has been speculated that the phytochrome molecule in its active, far-red-absorbing form binds to an unidentified receptor protein and that dormancy might be quantified directly by the amount of this protein present in the seed.\(^3\) Current research into the mechanisms and differences in gene expression between dormant and nondormant seeds is likely to revolutionize not only our
understanding of seed dormancy, but perhaps also the way we measure it.

At the time of writing, however, dormancy is usually measured by non-germination of imbibed viable seeds with adequate aeration and at a suitable temperature for seedling growth. If \( V \) is percentage viability of a seed lot and \( G \) the percentage germination in such conditions, then the percentage dormancy is \( (V - G) \). Germination and viability are both quantal responses since an individual seed is either viable or inviable and it either germinates or does not. By inference, the expression \( (V - G) \) likewise but incorrectly quantifies dormancy as a quantal response since an individual seed has to be classified as either dormant or nondormant. In reality, it is only the expression of dormancy in the specific testing environment that is a quantal response.[1] Bradford[6] has proposed that dormancy in an individual seed is like "a hill that seeds approach from one side (i.e. as the requirements to break dormancy are met) and then progress down the other, gathering momentum (increasing germination rate)."

The realism of this view is seen easily when considering the response of seeds as a function of the dose of a dormancy-breaking stimulus. Nondormant seeds in the population should germinate upon imbibition. The dormant seeds vary in dormancy: Some may respond to after-ripening for one week while others may need two (Fig. 1). It is well stated: "We do not yet know how to measure the depth of dormancy in individual seeds but its variation is reflected in the seed-to-seed variation in the expression of dormancy in a seed population."[1]

**Seed-to-Seed Variation in Dormancy**

Unless 0% or 100% of seeds germinate, the classification of viable seeds into two groups—that those that germinate and those that do not—may be thought to imply polymorphism. But polymorphism should be deduced only if there is a discontinuity in dormancy periods or when developmentally or morphologically different seeds vary in the depth of primary dormancy. Polymorphic seeds may be produced on the same or different plants. In the classic case of *Xanthium pensylvanicum*, the two seeds in each capsule are dispersed together. The upper seed is much more dormant and germinates at least 12 months later than the lower one.[2]"
dormancy percentages to probits (Fig. 1). This (probit) analysis gives a robust measurement of seed dormancy: The intercepts of the probit lines in Fig. 1 give far better estimates of dormancy levels of seeds produced in various maturation environments than the results of a single germination test. The reciprocal of the slope quantifies the standard deviation of the dormancy response to the applied treatment in the seed population, and these two parameters are the key to modeling responses of dormant seeds to environmental variables.^[7,8^]

**PRIMARY DORMANCY**

Primary dormancy may simply occur because the embryo is immature so that germination is delayed pending further development as in the linear embryos of the *Ranunculaceae* and *Umbelliferae*.^[4^] Other seeds are dormant due to a physiological block caused by the seed coat and/or the embryo.

Primary dormancy has two main functions: first, preventing precocious germination,^[9^] a response linked to the presence of abscisic acid (ABA) during seed maturation; and secondly, assisting the temporal dispersal of seeds by preventing their immediate, synchronous germination. Very few species can therefore reproduce effectively without seed dormancy. One exception is recalcitrant seeds from the tropics. These seeds can neither be dried nor be chilled below 10–15°C without losing viability. Primary dormancy is absent and germination occurs on or before release from the inhibitory effect of the enclosing maternal environment.

Heritability of dormancy is complex because parts of the seeds differ genetically. For example, a diploid embryo may receive nutrients from a triploid endosperm (with two maternal and one paternal sets of chromosomes) and is surrounded by maternal tissues (testa and fruit structures).

Primary dormancy not only varies with genotype but also with maturation environment; in barley (*Hordeum vulgare*) and *Cenchrus ciliaris* (a perennial grass that

---

**Fig. 2** Germination of *Orobanche aegyptiaca* seeds after conditioning (fully imbibed) for various periods at 10°C, 15°C, 20°C, 25°C, and 30°C. Seeds were surface-sterilized with sodium hypochlorite solution before conditioning for periods shown on the x-axis. Germination tests lasted ten days at 20°C with 3 ppm of GR24. GR24 is an analogue of Strigol—an exudate of cotton roots that stimulates germination of seeds of some parasitic plants. Loss of primary dormancy over the first 15 days (approx.) is followed by induction of secondary dormancy. Primary dormancy is lost most slowly and secondary dormancy induced most rapidly at 10°C. Secondary dormancy is induced most slowly above 20°C, the more rapid declines in germination at 25 and 30°C being due to loss of viability, which was most rapid at 30°C. (Drawn from data published in Ref. 8.)
occurs in arid and semiarid environments), dormancy was greater for seeds produced under water stress, a characteristic which may be of adaptive value in plants growing in arid ecosystems (Fig. 1). The opposite effect of water stress occurs in *Avena fatua*.

Primary dormancy declines both prior to shedding and subsequently. When this loss of dormancy occurs in "air-dry" seeds, it is termed after-ripening (Fig. 1). The rate of after-ripening increases with temperature in a predictable manner, the $Q_{10}$ for the relation usually being 2.5–3.8.[1]

**SECONDARY DORMANCY**

Dormancy may be induced in dormant and in "quiescent" nondormant seeds after shedding. Secondary dormancy is induced rapidly by anaerobiosis and more slowly by prolonged moist aerobic treatments in which germination does not occur. Induction of secondary dormancy may be delayed or prevented by intermittent low-intensity laboratory light and nitrate.[1] Rates of induction of secondary dormancy of *Orobanche* seeds were fastest at 10°C and decreased to a minimum above about 20°C (Fig. 2).[8] By contrast, rates of induction in imbibed *Rumex crispus* seeds increased with an increase in temperature.[1]

Are the mechanisms of primary and secondary dormancies the same? Dry after-ripening and the same chemicals may relieve both primary and secondary dormancy, implying some similarity. It is, however, interesting that while short periods of imbibition are associated with relief of primary dormancy, longer periods lead to secondary dormancy (Fig. 2). The final answer to this question may come when the expression of dormancy genes can be measured in seed lots varying in dormancy.

Annual cycles in which physiologically based dormancy is relieved and secondary dormancy induced during the course of a year occur in buried seeds of some annual plants in both temperate and tropical soil environments.[4] Exposure to light, nitrate, and temperature treatments may be needed to relieve residual primary and secondary dormancy at times of low dormancy. Understanding how these physical and chemical factors affect seed populations with different levels of dormancy is crucial if seedling emergence from persistent soil seed banks is to be predicted.[10]

Seed Genebank: Functions, Acquisition Strategies, and Database Management

Adi B. Damania
GRCP, University of California, Davis, U.S.A.

INTRODUCTION

When American poet Edgar A. Guest bought a packet of seed it flashed through his mind that he had purchased “a miracle of life.”

The seeds were worth only a dime but possessed a power no man could create, a dime’s worth of mystery, destiny, and fate.

—“A Package of Seeds”

In working with seeds, whether it is harvesting, cleaning, handling, storing, or transporting, it is essential to keep in mind at all times that inside the seed is a dormant miniature plant awaiting the opportunity to continue its life cycle. Crop genetic diversity can be conserved as DNA, clones, tissue culture, and living plants. This entry deals with genebanks that conserve genetic resources in the form of seeds only.

The principal reasons to conserve crop genetic resources in genebanks (genetic resources centers) are to save them for future use in plant breeding programs, to offer food solutions in times of famine or other natural disasters, and for biological research. Today, genetic diversity is under threat, whereas it was grown undisturbed for thousands of years. Habitats of wild progenitors of crop plants continue to be destroyed by unsustainable human activity in several places.[2] Also, in some areas, high-yielding cultivars are replacing traditional varieties (called landraces) developed by farmers’ selections over a millennium. As new varieties, with higher yields and greater disease resistance become available, landraces are displaced and lost forever if not collected and conserved in genebanks. This is especially ironic because all plant breeding is built on existing genetic diversity; hence, it is imperative that this diversity be conserved and remain available for present and future crop improvement programs and to ensure food security.

VAVILOV ESTABLISHES A GENE BANK IN SOVIET UNION

At various stages in human history, before there were genebanks, people have been collecting and conserving plants for their economic or exotic values in botanic gardens or plantations. However, the activity of mounting targeted expeditions overseas to scientifically collect crop germplasm from areas where its diversity is the greatest was pioneered by the Russian botanist, geneticist, and plant breeder Nikolai Ivanovich Vavilov (1887–1943). In a series of adventurous expeditions, mainly between 1916 and 1933, Vavilov and his coworkers collected more than 250,000 plant accessions from centers of diversity all over the world for the betterment of Russian agricultural production.[14] The collections that Vavilov made have been preserved by the N.I. Vavilov Institute of Plant Industry (VIR) in St. Petersburg, Russia. VIR houses one of the world’s oldest and most comprehensive genebanks.

Among the most important crop genetic resources collections are those held by the International Agricultural Research Centers of the Consultative Group for International Agriculture Research (CGIAR). The materials in their genebanks are held “in trust” for the United Nations’ Food and Agriculture Organization (FAO). More than 700,000 accessions are held at 11 CGIAR Centers, out of which 532,500 accessions are held “in trust.”

IN SITU AND EX SITU CONSERVATION

There are two basic technologies for storing seeds of crop genetic resources in situ, i.e., in its natural agricultural habitat, and ex situ, as stored seed samples or plants in a genebank.[11] A crop genebank is a facility for conserving, managing, and reproducing the diversity of crop plant varieties and their progenitors and/or wild and weedy relatives. Not unlike the crops they conserve, genebanks come in different shapes and sizes from very large number of collection samples (also referred to as accessions) conserved in specially designed buildings with cold storage rooms or a household freezer to a field consisting of a few labeled plants. However, their primary purpose remains the same: the safe maintenance of plant diversity.[6] A genebank may include the diversity of a single crop species and its wild relatives, for example, 35,500 or more samples of wheat and its wild relatives, gathered from around...
the world are maintained by the Genetic Resources Unit of the International Center for Agricultural Research in the Dry Areas (ICARDA) in Syria. National governments also maintain genebanks, such as the United States Department of Agriculture (USDA), Agricultural Research Service (ARS), National Plant Germplasm System (NPGS) that has over 458,000 samples of more than 10,376 species belonging to 1622 genera of genetic resources in storage at various genebanks.\[10\]

In the 1960s, the start of the genetic resources conservation movement consisted of but a handful of genebanks, mostly in the industrialized countries. Today there are nearly 1470 genebanks worldwide; nearly two-thirds of these are in developing countries.\[5\] At least 100 countries maintain living plants in field genebanks, and about 60 have facilities to conserve germplasm in vitro (in test tubes). Collections of fruit trees, such as mango, avocado, pecan, lychee, sugar cane, annonas, and cacao are conserved as living trees, usually clonally propagated in clonal repositories. Among them, the world’s genebanks maintain more than 6 million accessions. More than one-third of the total accessions are held by 15 national genebanks worldwide (for a comprehensive list see appendices in Ref.\[12\]).

**FUNCTIONS OF A MODERN GENEBANK**

1. Acquires and documents genetic resources.
2. Conserves and generates/multiplies samples of genetic resources acquired through collections, exchanges and donations.
3. Promotes and supports research activities related to plant genetic resources conservation and utilization.
4. Maintains a query-friendly database and documentation of the collections through networking.
5. Distributes plant materials between national and international institutions and scientists.
6. Disseminates information on evaluation results and other research through publications.
7. Sponsors training and workshops.
8. Collects data on morphology and other constant traits or characterization.
9. Evaluates collections for agronomic and other economically useful traits.

A flow chart of activity in an active genebank is given in Fig. 1.

Meeting the germplasm requirements of breeders is one of the most important functions of genebanks, but increasingly genebanks are fulfilling bigger roles. In addition, genebanks resupply farmers, through their local government or distribution system, with seeds collected previously from their own areas after a natural or man-made calamity. For example, repatriation of accessions to their country of origin is valuable in cases where local collections have been lost. This is the case in Iraq.

**ACQUISITION OF GERMPLASM TO START A GENEBANK**

When a genebank is newly established, it usually builds up its collections by soliciting donations followed by exchange. Thus, when ICARDA decided to set up a genebank, it got material from the USDA as well as the National Research Council’s (CNR) Germplasm Institute in Bari, Italy. Later, it sent out its own scientists on collecting missions and thus filled gaps, both geographical and morpho-types, in its collections. Materials are exchanged with other genebanks in both hemispheres. In recent years, the genebank at ICARDA and other international centers of the CGIAR have duplicated their collections at other international genebanks for reasons of safety. This is a standard practice among major genebanks known as safety duplication or “black box” conservation. Most genebanks also maintain a herbarium of plants or plant parts that are dried and preserved on herbarium sheets. These accessions are used to document the names and morphology of plants along with dates, detailed coordinates of the collection sites, and the names of collectors.

**SEED STORAGE REQUIREMENTS**

The most widely grown food crops, such as wheat, rice, and maize, have seeds that can be stored on a long-term basis. The major factors that influence the longevity of seeds in storage are temperature, moisture content, and oxygen concentration.\[13\] These three factors have to be considerably reduced to maintain germination ability over a long period of time, i.e., several decades. Seed viability is not static and it depends on the conditions of initial storage. Viability, which is normally near 100% when seeds are first stored, declines over time, so that they must be regenerated by growing plants in the field or a greenhouse to provide fresh stocks. In addition, depleted stocks of seed due to fulfilling requests have to be replenished. Hence, they need to be rejuvenated and multiplied, preferably at the same time.

At a genebank, the seeds are initially cleaned and subsequently dried to less than 6% moisture content, and sealed in a jar or glass vials, or in an aluminum foil packet from which air has been removed by vacuuming.
Under what is called medium-term storage, the seeds are maintained at about 5°C and can remain viable anywhere from 10 to 30 years. In some cases, when samples are often requested by breeders or other scientists, the seed material may not be kept in hermetically sealed containers, and hence humidity control is needed. However, for long-term storage, which may extend up to a 100 years, they are kept at −18°C in air tight containers (e.g., sealed tins, glass ampoules, aluminum foil pouches, etc.). In this case, humidity is not controlled because the samples are hermetically sealed. For a list of procedures for handling seeds in a genebank see Refs. [3,4,7].

Finally, a wide range of plants and particularly tropical trees produce seeds that are in various ways “recalcitrant.” They are so termed because they are very difficult to germinate and do not maintain viability like orthodox seeds under low humidity and below freezing temperatures. This is largely due to their thick seed coats. Hence, seeds from recalcitrant species require more elaborate methods of preservation, most often by maintaining living plants that must be tailored individually to their requirements. The principal characteristic difference between orthodox and recalcitrant seeds lies in the physiology of their response to desiccation. [1] Hanson [7] prefers to use the more accurate terms “desiccation-tolerant” for orthodox seeds and “desiccation-sensitive” for recalcitrant seeds.

**SEED HEALTH**

Seed material acquired through collection in the fields or through donation from other genebanks may be infected with pathogenic organisms, and care must be taken that these pathogens do not cause problems in the country where the receiving genebank is located. [8] Subsequently, the samples are tested for seed or plant health by germinating the seeds and observing the plants for diseases before being put in to long-term storage. If there are risks of introducing a disease, the genebank may be required to generate the seed in quarantine [12]. In some countries, seed treatment by sterilizing in hot water or an antiseptic is done before the seeds can be entered into a genebank.
INFORMATION MANAGEMENT

Genetic resources are as useful as the amount and quality of the data related to them. Information on each accession in a genebank is maintained in computerized databases. These databases are queried to recover passport, descriptor, and evaluation data rapidly to make selections. Practically, all database systems in use are relational databases. Earlier, there were hierarchical databases and network databases, but nowadays we have mostly relational databases and a few object databases. Different types of relational database management systems (DBMS): Oracle, dBASE, FoxPro, Access, etc. are available. Genebank managers use different DBMS to implement desired applications. There is no common “application” for genetic resources databases. For example, the USDA Germplasm Resources Information Network (GRIN) is based on Oracle software, whereas ICARDA uses a system based on Visual FoxPro software. Also on Microsoft SQL server, many smaller national germplasm documentation systems are based on Access. This is not necessarily a problem since transfer of data from one DBMS to another is possible. The System-wide Information Network for Genetic Resources (SINGER) system is a database periodically “populated” from various germplasm database systems used in different CGIAR Centers for the purpose of joint web publishing. In Europe, there are quite a number of diverse systems in use. All this makes the job of the documentation specialist at any genebank very difficult, especially when evaluation information needs to be exchanged.

There are practically little or no difficulties in sending so-called passport information with a set of requested or exchange samples. The passport data contain a few simple descriptors such as crop number; genebank number; Latin name (botanical name); country of origin; province; site (of collection), latitude, longitude, and altitude of collection; plus identifiers (local name of variety or landrace); accession number(s) of other genebank(s) if the sample was received as a donation from another genebank (Jan Konopka, pers. comm.). Three distinct points must be noted here: 1) adequate information must be acquired and easily accessible; 2) this database of information should be developed or processed for optimal use by breeders and other users; and 3) any decision making regarding the ex situ conservation in genebanks incorporates or takes into consideration this information.

INTRODUCTION

In nature, seeds overcome three major problems for the plant. First, they are the method of multiplication, because a plant is often able to produce very large numbers of seeds. Second, seeds are a survival mechanism for plants because they often survive in the soil, even under adverse conditions, persisting until suitable germination conditions occur. Third, seeds help to disperse plants using agencies such as wind, water, or contact with animals or birds.

In agriculture, the aim of seed production is to multiply seed numbers by establishing a seed crop with sufficient plant density to produce seed to sow new plantings in the following season.

VEGETATIVE AND REPRODUCTIVE DEVELOPMENT

Plants are reproduced in two main ways for use in agriculture. Some are reproduced vegetatively (e.g., potatoes, cassava), although most produce seed by sexual reproduction (e.g., self-fertilization or cross-fertilization). A few crop species reproduce by apomixis, which is asexual but produces seedlike bodies that behave in all respects like normal seed (i.e., reproduction without fertilization)\(^1\) (Fig. 1).

Before seeds can be produced the plant must have the chance to flower. Some plants pass through the vegetative stage to the reproductive phase with no special requirement or stimulus. In other plants, there is a clearly defined transition between the two phases. The early stage (before the plant is receptive to an external flowering stimulus) is the juvenile phase. Attainment of the required physiological phase (“puberty”) is related to plant size (to leaf numbers in particular). At this stage, plants are often stimulated to become reproductive by day length (photoperiod) and/or by exposure to low temperature (vernalization). As a result, there are plants with no required climate stimulus (most annuals) and those that require precise things to happen in terms of low temperature (most perennials) and day length (long-day, short-day, or day-neutral plants).\(^2\) The timing and prediction of flowering in a range of crops is well discussed elsewhere.\(^2\)

Flower morphology, pollen formation and pollination, and fertilization are well described in field crops by Copeland and McDonald\(^3\) and in vegetable seed production by George.\(^4\) A schematic summary of the seed production sequence is shown in Fig. 2.

SEED DEVELOPMENT

In seed crops the sequence of seed development occurs in three stages.\(^5\)

- A growth stage, lasting about 10 days after pollination and characterized by rapid increase in cell division (but not elongation) in cell division, high moisture content, and nonviability (Fig. 3A).
- A food reserve accumulation stage, lasting 10–14 days and involving a great increase in seed dry weight that reaches a maximum at the end of the stage (Fig. 3B). The amount of water in seed changes little but the percentage water content falls rapidly. Seed becomes viable during this stage, which ends with seed becoming physiologically mature.
- A ripening stage, lasting 3–14 days, depending on climate. Seed dehydrates to a moisture content in equilibrium with the environment, resulting in seed that has reached harvest maturity.

SITE SELECTION AND CROP MANAGEMENT

Choice of a seed production site is a basic consideration. It is important because different areas vary in their suitability for seed production. The main requirements are to grow seed crops in areas that have a sufficiently long growing season and suitable day length and temperature to promote strong vegetative growth; strong stimulation of seed head development and flowering; and good climatic conditions during seed development, ripening, and harvesting.

In forage crops, plant breeders have been very successful in producing varieties that grow large amounts of herbage. This is done in many cases by breeding plants that remain vegetative (leaf producing) as long as possible before becoming reproductive (i.e., seed producing).
The objective in specialist seed production systems is to grow large plants, producing flowers and then seeds at as many of the available sites as possible.

Growers who produce seed crops with high yield and quality tend to be those who manage their seed crops to force plants to become more strongly reproductive.¹⁶ Seed management packages are recommended that involve judicious, well timed use of fertilizer (e.g., P and K in legumes and N in grasses); controlled use of water; cutting or grazing to encourage plant branching and provide more places on the plant for flower formation; adjustment of sowing date and rate to take advantage of differences in climate (temperature and day length); specialist herbicides to remove specific weeds; and plant growth regulating chemicals.

**CROP ROTATION AND Paddock HISTORY**

Time intervals between related or similar crops are standard agronomic practice. The many reasons for crop...
Schematic summary of seed production sequence.

**Vegetative growth (2 – 6 months)**
- Nutrition and water important
  - Plant increases in size
  - Plant may need low temperatures/short days
  - Plant develops sites where reproduction will later occur (Fig. 1A)

**Response to daylength and temperature**
- Grasses – growing points form buds, then seed heads (determinate growth) – (Fig. 1B)
  - Vegetative growth of reproductive tillers stops
- Legumes – growing points form buds and flowers (indeterminate growth). Vegetative growth usually continues during flowering and seed development (Fig. 1C)

**Flowering, pollination, fertilization 20 – 40 days**
- Affected by temperature, disease, moisture
  - Self or cross pollination
  - Pollinating agents – wind, insects

**Seed development 20 – 40 days**
- Increase in seed weight
  - Reduction in seed moisture
  - Changes in seed color
  - Seed shattering
  - Increase in seed germination

**Fig. 2** Schematic summary of seed production sequence.

Rotation include plant nutrition; maintenance of soil condition; reduction of disease, pest, and weed seed carryover; and, particularly in the case of seed production, to minimize the risk of plant residues and dormant crop and weed seeds remaining in the soil from previous potentially contaminating crops. Information on previous cropping history is an important consideration in seed production.

Maintaining the genetic purity of the seed crop is also important. This is usually achieved by crop growth regulation and good planning. The major factor is to minimize the possibility of cross-pollination between different crossing-compatible crops. This is done by ensuring that crops likely to cross-pollinate are not flowering at the same time or are planted an acceptably safe distance apart to prevent pollen crossover.
Seed fields, whether they involve an autumn- or spring-sown crop, may be established in rows or in solid stands. The former has the advantage of requiring lower seed sowing and fertilizer rates, and often ensures cleaner weed-free crops and longer stand productivity. Seeding rates lower than those for general crop production are often advocated when crops are sown for specialized seed production. Small seeded grasses such as bentgrass are often sown at 0.25 kg/ha, whereas larger cereals may be sown at 80–100 kg/ha.

**PLANT POPULATION**

In many seed crops the successful establishment of an adequate or optimum plant density is directly related to high seed yields. With increasing population, the yield of seed per hectare increases to a maximum point or plateau before declining. This parabolic relationship suggests that in seed production, the sowing rate should be sufficient to establish a crop that will produce a seed yield maximum.\(^6\)

Row spacing depends on plant growth habit and the lateral spread of the root system. Taller plants are often grown in wider rows than are shorter plants.

**WEEDS**

Weeds are objectionable in all crops because they compete for soil, water, and nutrients; smother the crop and cut out light; may delay harvesting; may impede cultivation and harvesting; and may be plant parasites (e.g., dodder (Cuscuta sp)) or hosts for pests and diseases. Their seed may ripen at the same time as the crop and be difficult to remove in seed cleaning (e.g., wild red rice in rice; wild oats in cereals).

Weed control measures include crop rotation, sowing into a clean seedbed, application of presowing or pre-emergence herbicides, inter-row cultivation, rogueing, and sowing clean seed.

**PESTS AND DISEASES**

The incidence of diseases and pests in a seed crop is affected by climate, their presence in the soil or in the sown seed, and by the presence of alternate hosts growing nearby or in the field. Such control measures as crop rotation, burial of plant debris, seed treatment, foliar sprays (noting risks to pollinating insects if using insecticides), isolation, rogueing, and postharvest hygiene all deserve consideration.

**MOISTURE**

Moisture stress can reduce seed yield. On the other hand, irrigation can ensure good establishment and vigorous vegetative growth, and ensure that the plant is not stressed for moisture during seed development. Despite this, the induction of some moisture stress immediately flower buds form can be helpful in reducing the protracted flowering period in indeterminate plants (e.g., in legumes such as white clover (Trifolium repens)).

**HYBRID SEED PRODUCTION**

The discovery of hybrid vigor in field crops such as maize in the early 1900s has probably contributed as much to seed production as any other single factor.\(^1\) A hybrid is produced by crossing inbred lines that have been developed by inbreeding and selection. This results in hybrid seed progeny with greater yield than nonhybrid crops. This occurs due to heterosis or hybrid vigor, due to an accumulation of a large number of dominant factors (genes) that favour growth. Hybrid seed production is now common in many field crops (particularly cereals) and in the production of vegetable seeds.\(^4\)
CONCLUSION

Perhaps the most surprising thing about many of the crops grown for seed is the low yields obtained, compared to the potential yield these crops could produce if all components were maximized.\textsuperscript{[6]}

As an example, the theoretical potential seed yield for alfalfa (Medicago sativa L.) is about 12 tonnes/ha and for Trefoil (Lotus corniculatus L.) about 2500 kg/ha. These can be compared with mean actual seed yields in New Zealand of 670 kg/ha (6\% of potential) and 540 kg/ha (22\% of potential).

This suggests many farmers still have a long way to go before realizing the production potential of the crops they grow for seed.

Seed Testing Methods

Daniel G. Curry
Iowa State University, Ames, Iowa, U.S.A.

INTRODUCTION
A similar group of seed that is stored together, is uniform in genetics, and has a similar production history is known as a seed lot. Each seed lot has a certain amount of value, depending on the amount of seed in the lot and its quality characteristics. Most of these characteristics cannot be determined by visual inspection. Therefore it must be tested using various procedures to determine the quality of the seed and, ultimately, its value. Seed companies rely on these tests to ensure they are selling seed that meets not only the government’s minimum standards but also their higher standards of quality. Customers rely on these tests to determine if the seed is of good value.

SEED REGULATIONS
To ensure fair trade, most countries require that specific seed tests be performed and documented. For example, in the United States, the seed laws direct seed companies to label their seed when it is sold, communicating to the buyer pertinent information concerning its quality (Fig. 1).

Most seed laws require that only a minimum number of tests be performed and the results be reported on the label. However, many seed companies need additional information on quality characteristics that are beyond the minimum requirements to ensure customer satisfaction and loyalty. For example, vigor tests cause stress on the seed, and the results may indicate how well the seed lot will perform under environmental stress. This information is important to companies whose customers plant in cold or wet environments.

WHO TESTS SEEDS
Seed tests are performed by analysts at university, provincial, state, and federal government laboratories as well as technologists at commercial and private laboratories. Seed testing personnel analyze seed according to established rules that are based on past experience and scientific research. These rules are recorded and updated periodically by various organizations.

SAMPLING
It would be impractical to sample every seed in a lot, because frequently the seed is unusable afterward, and testing large amounts of seed would not be timely or economical. Therefore a sample of the lot is taken and submitted for testing. If the sampling technique is sound, the sample will represent the entire lot. The number of seeds tested depends on which test is being performed (Table 1).

TYPES OF SEED TESTS
Important quality characteristics of seed include germination (does it grow?), physical purity (what else but pure seed is in the lot?), seed health (are there pathogens in or on the seed?), varietal purity (is there more than one variety in the lot?), and genetic purity [does the seed contain genetically modified organisms (GMOs)?].

In seed laboratory practice, germination is defined as the emergence and development from the seed embryo of those essential structures which, for the kind of seed in question, are indicative of the ability to produce a normal plant under favorable conditions. While many factors affect germination, the most important are proper moisture, temperature, and sufficient oxygen (Fig. 2).

Documents that contain scientifically based methods of seed testing instruct analysts how to control factors that would induce the maximum germination. Seed is planted into a specified media, with proper moisture added, and placed in a germination chamber at the proper temperature for a specified number of days. Germination of most seeds takes from 7 to 28 days. At the end of this period, the seedlings are categorized as normal or abnormal, and the ungerminated seeds are categorized into dormant, hard, or dead seed. This information will be reported to the seed company. The germination result is given as a percentage (the average number of seedlings considered normal out of the entire number of seeds planted) and is valid for a period of months.

The purity test is performed by physically separating the pure seed from other crop seed, weed seed, and inert material. A magnifying lens or a microscope often is used to help the analyst view all components of the sample.
With forceps in hand, the analyst "works" the sample (about 2500 seeds) by dragging a few seeds away from the sample and separating the material into the four components. The weight of each component is recorded in the final report, and the percentage of each component will be on the label when the seed is sold.

With the noxious weed exam, the amount of seed tested is usually 10 times the purity weight. A noxious exam is similar to the purity test, except only noxious weeds are removed. The weed seeds to be extracted are determined either by local or federal governments. The number of noxious seeds found in the working sample will be reported to the seed company.

There are many other types of seed tests that provide information about some aspect of the seed that is important to the owner. Viability tests are used to determine whether the seed is alive. Even under ideal conditions, some live seed may not germinate because of dormancy or seed hardness. A viability test, such as staining seed with tetrazolium salts, allows the analyst to separate the live seed from the dead. This test is useful when seed is experiencing dormancy. Although the seed may not germinate during the testing process because of dormancy or seed hardness, the tetrazolium test will indicate its viability.

Vigor tests determine how well a seed lot will perform under stressful environmental conditions. High and low temperature extremes or low-oxygen/high-moisture extremes are used to stress the seed. Final germination results from vigor tests usually correlate with extreme field conditions.

Seed germination performance can be affected by certain pathogens such as fungi, bacteria, viruses, and nematodes. Seed health tests are usually performed for one of two reasons: 1) The seed company wants to ensure

*The amount of seed tested varies, depending on the species of seed.
that a particular pathogen is not present so it will not affect the customer’s growing crop; or 2) the company wants to ship seed to another country. When shipping to another country, a certificate must be issued by the governmental phytosanitary offices of each exporting country. The certificate requires a declaration that states the seed is free of the importing country’s list of banned pathogens. For example, Mexico will not allow corn seed into the country unless that lot of seed has been determined to be free of bacteria known as Stewart’s wilt (Erwinia stewartii). Argentina will not allow imported corn seed into the country unless the seed is free of wheat streak mosaic (WSMV). More than 150 different tests can be performed to determine the presence of various pathogens in seed lots.

Three different methods are used to test genetic traits. For the first, a bioassay, detection is based on symptoms of the plants that are tested. Seeds or seedlings are made to absorb a chemical herbicide for a period of time. The seedlings are then evaluated for symptoms of the plant’s reaction. If the seedlings do not react to the herbicide, no symptoms appear and the seedling is thought to have the herbicide-resistant trait. If the seedlings are not tolerant to the herbicide, they will show symptoms, such as restricted growth. A minimum of 400 seeds are usually tested, and a percentage of the amount of seed that is tolerant or nontolerant is reported.

A second test for genetic traits uses the enzyme-linked immunosorbent assay (ELISA) method, which is based on detection of specific proteins. Two application methods use the ELISA technology. The first uses a plastic plate with 96 wells that contain an antigen for the target protein. Tiny liquid samples from the seed or plant tissue are placed in the wells. If the target protein is present, the wells change color. If not, the solution washes out and there is no color change. This method works well in a lab environment, as it requires the use of a computer-controlled plate reader, a sterile environment, and lab equipment such as a multi-channel pipette.

The other ELISA method uses a lateral flow absorbent strip. When this strip is placed in a solution of plant material and water, it will detect whether a protein from a particular genetic trait is present in the sample. This system works well in nonlaboratory settings such as crop fields, farm elevators, and other points of commerce.
where a quick, low-cost determination of GMO presence is needed (Fig. 3).

A third technique of detecting genetic traits is called the polymerase chain reaction (PCR) method. It amplifies a target sequence of genes that is present in the seed or seedling. If the sample contains a genetically modified gene, thousands of copies of the gene will be made, thereby allowing the analyst to detect the gene.

Variety tests are performed on seeds to ensure that the genetic integrity of the seed lot is secure. Plant breeders work to improve existing varieties of plants. The breeder starts with a small number of plants that have been genetically changed in some way. As each generation of plants is grown and the seed is produced, steps are taken to preserve the identity of the seed lot. Otherwise, seed tends to be commingled or contaminated by pollen from other seed lots. An example of a variety test is a hilum (point of attachment on the seed coat of a soybean seed) color test for soybeans. Five hundred seeds are compared with parent seed to ensure that the color of the hilum is similar in all of the seed.

CONCLUSION

As seed continues to be assessed for its quality characteristics, seed testing will remain an important part of agriculture. Germination, purity, noxious, and other similar tests will change little over the coming years. Genetic seed testing will continue to evolve, however, as new traits of plants are produced by the biotechnology industry.

INTRODUCTION
The concept of seed vigor arose following observations that, despite having equally high laboratory germination, commercial seed lots of many species show large differences in field emergence, particularly in adverse field conditions. Failure of the germination test to predict differences in field emergence suggested that there is a further physiological aspect to seed quality, not revealed by laboratory germination. This is referred to as seed vigor. Seed lots having high germination but poor emergence are low-vigor seeds; those giving good emergence are high-vigor seeds. Differences in germination rate and storage potential are also indicative of vigor and are included in the definition of vigor accepted by the International Seed Testing Association (ISTA). Seed aging and imbibition damage influence vigor and can be reduced by careful storage and handling of seeds. An understanding of the causes of vigor differences can help to maintain high levels of seed vigor.

DEFINITION OF VIGOR
In 2001 the ISTA formally recognized seed vigor as an important aspect of seed quality when it added vigor as a chapter in the International Rules for Seed Testing. The ISTA definition of seed vigor is as follows:

``Seed vigor is a sum of those properties that determine the activity and level of performance of seed lots of acceptable germination in a wide range of environments.

Seed vigor is not a single measurable property, but is a concept describing several characteristics associated with the following aspects of seed lot performance.

i. Rate and uniformity of seed germination and seedling growth
ii. Emergence ability of seeds under unfavorable environmental conditions
iii. Performance after storage, particularly the retention of the ability to germinate

A vigorous seed lot is one that is potentially able to perform well even under environmental conditions that are not optimal for the species.``

The germination of low-vigor seeds is therefore asynchronous and slow and the seeds emerge poorly in unfavorable conditions, in contrast to the rapid uniform germination and good emergence of high-vigor seeds. Low-vigor seeds also have poor storage potential.

CAUSES OF DIFFERENCES IN SEED VIGOR
Aging
Seed deterioration, or aging, is the major cause of differences in seed vigor and can be described as the accumulation of deleterious changes within the seed until the ability to germinate is lost. The aging of a seed lot is described by the seed survival curve (Fig. 1). This illustrates that the germination of a population of seeds initially shows a very slow decline with time during which it is difficult to differentiate between the standard laboratory germination of samples of seeds at different points on the survival curve. However, as the population moves along the survival curve, the seeds are aging, i.e., deleterious changes are accumulating, until, at the end of the slow decline, the proportion of seeds within the population that are incapable of germinating increases and germination falls. At the beginning of the initial slow decline in germination, seeds are described as physiologically young or high-vigor seeds, whereas at the end of this phase they are physiologically old or low-vigor seeds.

Aging may occur before harvest, both during and after postmaturation drying. The degree of preharvest deterioration, frequently described as ‘‘weathering,’’ depends on the climatic factors temperature and moisture (humidity/rainfall). Most deterioration occurs after the seeds have dried down to harvest maturity as a result of delayed harvesting.

The greatest incidence of aging arises, however, during seed storage, commonly in commercial storage, but also during brief, temporary periods of storage—for example, after harvesting and before and during processing. The major factors that influence seed aging and hence a decline in vigor and subsequently germination are seed moisture content and temperature. Their effects are described in Harrington’s Rules of Thumb, which...
state that a 1% increase in seed moisture content or a 5°C increase in storage temperature will double the rate of aging, i.e., halve the storage life. These relationships are described more accurately in the viability equation used to predict long-term storage of seeds in gene banks.

Imbibition Damage

Imbibition damage is a major cause of low vigor in grain legumes and arises when water rapidly enters the cotyledons during imbibition leading to physical disruption of membranes, cell death, and high solute leakage from the seeds, particularly at low temperatures. Imbibition damage highlights the role of the testa in protecting the cotyledons from the damaging effect of water uptake. In some species, an intact testa limits the incidence of imbibition damage. High-vigor seed lots have little testa damage, imbibe slowly, show little imbibition damage, and emerge well. Extensive testa damage is associated with rapid water uptake and low vigor.

In other grain legume species (e.g., Phaseolus sp., Cicer ciceris, Vigna sesquipedalis, Vigna unguicularis), there is a genotypic component to the susceptibility of seeds to imbibition damage. Cultivars having partially or completely unpigmented testae imbibe more rapidly and show greater levels of imbibition damage compared with cultivars having pigmented testae. As a result, the vigor of unpigmented cultivars is reduced, leading to poorer field emergence than is found in pigmented cultivars.

Interaction of Imbibition Damage and Aging

The two major causes of reduced vigor in grain legumes—aging and imbibition damage—also interact, aged seeds being more susceptible to imbibition damage. It has been proposed that the increased susceptibility of aged seeds to imbibition damage arises because membranes that have been weakened by physiological deterioration are more sensitive to physical damage during imbibition. [5,6]

ASSESSMENT OF SEED VIGOR

A range of tests evaluate seed vigor, the theoretical basis of which lies in seed aging. Vigor tests can be divided into three categories: physiological tests, biochemical tests, and tests that apply the whole aging process.

Physiological tests divide into two groups. In the first group, there are those tests that measure the impact of aging on an aspect of germination and early seedling growth. These are essentially a modification of the germination test and reveal the reduced rate and uniformity of germination that is found in aged seeds. Vigor can be assessed as the rate of germination based on the first count from the standard germination test. The slower germination of aged seeds also leads to smaller seedlings, when seedling size is assessed at a particular point in time, as in the seedling growth test. In the second group of tests, such as the cold test for maize and the cool germination test for cotton, stresses that reflect the type of stress that may be encountered in the field are applied to the seed. Low-vigor seeds are revealed by the reduced tolerance of aged seeds to stress.

The second category of vigor tests includes biochemical tests. The Conductivity test uses the increase in solute leakage that occurs from aged seeds to identify seed lots of low vigor. This test is an ISTA-validated test for garden peas and can also be applied to a wide range of grain legumes. The Tetrazolium test indicates the decline in respiratory enzyme activity during aging through the reaction of a colorless solution of 2,3,5-triphenyl tetrazolium chloride with dehydrogenases to produce the red substance, formazan, in living cells. Dead cells do not stain.

The third group of vigor tests evaluates the effect of a period of aging on germination and is based on the manipulation of the rate of seed aging by holding seeds at a raised temperature and high relative humidity (Accelerated Aging test) or moisture content (Controlled Deterioration test). Seeds age rapidly and reductions in germination, normally seen over months or years, occur within days or hours. Both tests predict the field emergence and storage potential of seeds. The Accelerated Aging (AA) test is ISTA-validated for soybean, while
Controlled Deterioration\textsuperscript{[6]} tests the vigor of small seeded vegetable species and is an ISTA suggested test.\textsuperscript{[7]}

**MAINTENANCE OF VIGOR AND VIABILITY**

Seed moisture content influences the rate of seed aging more than the temperature of storage;\textsuperscript{[4]} therefore, efficient drying of the seed at or after harvest is important to reduce the rate of aging during subsequent storage and prevent a decline in vigor. However, dry seeds have a low water potential and hence high matric potential and readily absorb moisture from the air.\textsuperscript{[9]} Thus, control of the relative humidity of the store is important to maintain low seed moisture content and reduce aging. Alternatively high-cost, low-volume seed may be stored in sealed moisture-proof containers.

Low-vigor seeds show earlier and greater reductions in germination during storage than high-vigor seeds in all storage conditions. Application of the Accelerated Aging or Controlled Deterioration test before storage enables seed producers to identify these low-vigor seed lots with poor storage potential.

Minimizing the incidence of testa damage during harvest and processing can maintain seed vigor by reducing the incidence of imbibition damage. Testa damage is greater when seeds are harvested at low seed moisture content. Modification of harvest timing and handling procedures can reduce testa damage and help maintain seed vigor.

**CONCLUSION**

Seed vigor has a major effect on successful emergence and crop establishment. Careful harvest and processing of seed offers one approach to maintaining seed vigor. In addition, application of vigor tests during production can identify where any reduction in seed quality has occurred during the production process, whether this is when the seed is still on the plant (weathering), during harvest and processing, or during storage. Thus, guidelines could be developed to minimize any reduction in vigor in subsequent years. In addition, companies may use vigor results in their in-house quality control. This could involve preventing the sale of particularly low-vigor seed or providing guidance regarding the storage potential of seed lots.

INTRODUCTION

Pathogen transmission through seeds occurs when pathogenic microorganisms spread from seeds to seedlings. A developing infected plant can show symptoms within a few days or develop asymptotically for a variable period of time. In some rare cases, pathogens present in infected plants survive, spreading from seeds to plants and from plants to seeds without causing any external symptom and inoculum production (i.e., Neotyphodium, grasses).

Most seed-transmitted pathogens (virus, bacteria, and fungi) in favorable conditions can cause very serious yield losses. For example, Drechslera maydis race T (southern leaf blight of corn) in the United States (1970) caused losses of about one billion dollars.

In plant pathology, seed transmission represents a possible mode of primary infection from which dangerous polycyclic microorganisms can start epidemic attacks. The early presence of a small quantity of infected plants (i.e., 0.05% of a crop) is sometimes sufficient for the development of destructive attacks (i.e., viral and bacterial diseases of legumes and vegetables). In some host-pathogen combinations seed transmission occurs every year because seeds represent the only possibility for the organism to survive (i.e., loose smut of wheat). In others this phenomenon occurs sporadically, because pathogens normally survive with other modalities (i.e., soil, other hosts, volunteers and wild plants, etc.). The different types of seed transmission are summarized using different criteria. Some of these diseases (i.e., ergot, bunt, and smut of cereals) were studied some centuries ago by plant pathology pioneers. With the increasing importance of seed pathology and the application of improved methodologies for microorganism detection in seed lots, more diseases were found to be seed transmitted.

MECHANISMS OF PATHOGEN TRANSMISSION AND REPRESENTATIVE EXAMPLES OF IMPORTANT DISEASES

Nine mechanisms of seed pathogen transmission are reported in Table 1.[1] The first six are determined according to the three possible inoculum locations in the seed (intraembrial, extraembryal, and contamination) and the two types of plant infection (local and systemic). The other three are represented by seed contamination with a particular nonparasitic stage of the pathogen in the soil before causing local, systemic, or organospecific infection of the plant.

1. Intraembrial infection causing systemic infection of plants. Ustilago nuda, barley (loose smut). When the seed germinates, the fungal mycelium located inside the embryo (mainly in the scutellum) moves to the growing point and then to the young tillers. The mycelium is carried up the plant with its elongation. The first symptoms of the disease appear during spike differentiation, when the teliospores of the fungus replace the seed and are released for the infections of healthy spikes. Embryo infection followed by systemic infection has been observed to be caused by other fungi (Plasmopara helianthi, sunflower, Fig. 1), viruses (i.e., Bean common mosaic virus, bean, Soybean mosaic virus, soybean), and bacteria (i.e., Xanthomonas axonopodis pv. phaseoli, bean (Fig. 2), Xanthomonas campestris pv. vesicatoria, pepper (Fig. 3)).

2. Intraembrial infection causing local infection of plants. Ascochyta pisi, pea (anthracnose). The mycelium, localized in the embryo, causes lesions on the first true leaves where pycnidia develop under suitable humidity conditions. The spread of conidia by the wind causes the secondary infection of healthy plants.

3. Extraembrial infection causing systemic infection of plants. Ustilago avenae, oat (black loose smut). The mycelium, localized in the embryo, causes lesions on the first true leaves where pycnidia develop under suitable humidity conditions. The spread of conidia by the wind causes the secondary infection of healthy plants.

4. Extraembrial infection causing systemic infection of plants. Ustilago avenae, oat (black loose smut). The mycelium, present in the pericarp, develops in the young seedling, causing systemic infection of the plant. During the flowering period, the behavior of the fungus is similar to U. nuda (see first mechanism). In Xanthomonas arboricola pv. malvacearum, cotton, the bacterium, localized mainly in the seed coat, causes systemic infections and the first symptoms on the cotyledons (Fig. 4).

5. Extraembrial infection causing local infection of plants. Septoria apiicola, celery (late blight). The pycnidia present in seed coat and pericarp produce conidia that spread to cotyledons and young leaves where local dark lesions may appear after about 10...
days. In favorable conditions, the fungus may produce new pycnidia for the prosecution of its life cycle. A similar mechanism has been recently observed on *Alternaria linicola*, linseed (Fig. 5) and on *Stemphylium herbarum*, red cichory (Fig. 6).

5. Seed contamination causing systemic infection of plants. *Tilletia caries*, wheat (common bunt). Teliospores of *Tilletia caries* are localized on the surface of healthy wheat seeds, where they overwinter. At the time of grain germination, teliospores germinate, producing a dikaryotic hypha that penetrates into the cells of the emerging coleoptiles, reaching the base of the first and second leaves and then the area below the growing point. The infection cycle proceeds asymptomatically, until the production of an ear with kernels that contain the teliospores.

6. Seed contamination causing local infection of plants. *Puccinia carthami*, safflower (rust). Safflower rust is

a rare seedborne rust disease transmitted directly from seed to seedling. Teliospores that contaminate the surface of seeds are responsible for the infection of seedling tissues, causing hypertrophy and hyperplasia of hypocotyls (Fig. 7). The inoculum produced above ground spreads to the leaves, where it causes the typical rust symptoms (pustules).

7. Seed contamination followed by a period of saprophytism or by a dormant stage in the soil and then by local infection. Sclerotinia sclerotiorum, sunflower (basal stalk rot and head rot). Sclerotia of the fungus, introduced into the soil by the seed, can produce hyphae that can either infect the developing host or generate apothecia, asci, and ascospores. The ascospores released in the environment are responsible for local infection of different part of the host, including the head.

8. Seed contamination followed by a period of saprophytism in the soil and then by systemic infection.

Fusarium oxysporum f.sp. callistephi, aster (wilt). Conidia and mycelium of the fungus, carried into the soil by the seed, grow saprophytically in the soil, increasing the inoculum level. In favorable conditions, the fungus attacks the roots of young seedlings and develops inside the plant, causing vascular wilt. In Fusarium oxysporum f.sp. gladioli, saffron (Fig. 8), the same mechanism has been observed.

9. Seed contamination by structures from organospecific seed infection followed by an extramatrical non-parasitic phase and later by direct organospecific seed infection. Claviceps purpurea, cereals (ergot). Sclerotia of the fungus, transported into the soil by the
seed, remain inactive until the spring when they produce several club-shaped perithecial stromata containing asci and ascospores. Ascospore dispersal occurs during the flowering period of the host when the ovary is susceptible to the fungus, prior to fertilization.

FACTORS AFFECTING THE TRANSMISSION OF SEEDBORNE PATHOGENS

The presence of pathogens in seed lots does not always involve microorganism transmission to the plant in the field and disease development. Research carried out in different host–pathogen combinations showed the importance of some parameters that influence the infection of young seedlings until the development of the first symptoms. A number of factors such as host, pathogen, environmental conditions, and crop management may affect the transmission rates of seedborne pathogens.[2–5]

1. Host Genotype. The development of seedborne infection in the field depends on the genetic constitution of the host cultivar. In plant-resistant genotypes, the activation of defense mechanisms in germinating infected seeds can prevent disease transmission to the plant. Resistance of wheat to loose smut fungus occurs through the reaction of the embryos, which are completely resistant to infection. In other host–pathogen combinations, some cultivars show less susceptibility than others because they require a major quantity of inoculum with respect to the susceptible cultivars (i.e., Tilletia tritici, wheat).

2. Quantity of Inoculum. The inoculum level can affect pathogen seed transmission because too little or too much inoculum can result in nontransmission of the disease. For example, in Tilletia caries, wheat, infections of seedlings in susceptible cultivars occur when the number of teliospores contaminating the seeds is more than 100 per seed. The quantity of inoculum associated with the seed depends on the different situations occurring during seed differentiation. For example, late flower infections may result in low superficial contamination of seeds only (i.e., Septoria spp.). On the other hand, early infections of flowers may cause severe infections of developing seeds, reducing seed vitality: Seeds fail to germinate and do not transmit the disease (e.g., poor quality of cereal seeds infected by Fusarium spp.). Between these two extreme situations, cultivar resistance, germination capacity of seeds, and environmental conditions at sowing time determine the amount of inoculum necessary for seed transmission.

3. Inoculum Vitality. Inoculum vitality depends on the longevity of the peculiar structures produced by the pathogens and on the characteristics of each seed lot (Table 2). Mycelia, sclerotia, chlamydospores, oospores, teliospores, virus particles, and bacterial cells that contaminate or infect seeds can maintain their vitality for some years (i.e., 5–10 or more). Often, vitality depends on the quantity of inoculum present in each seed lot and can be reduced by soil microflora (or other factors) when seeds are sown.
4. Type of Inoculum. Seed transmission can be influenced by the type of inoculum in seeds because not all the pathogenic structures present in the seed lots can infect the developing seedlings. Safflower seeds by contaminated uredospores of *P. carthami* produce healthy seedlings, whereas teliospores produce the typical symptoms of the disease.

5. Inoculum Location in the Seed. Often, seed transmission occurs only if the inoculum is located in a particular position of the seed. Most viruses, for example, are transmitted to the seedlings only if they are located in the embryo.

6. Soil Microflora. The microflora present in the soil can reduce the transfer of vital inoculum from seeds to seedlings, especially when the contaminating inoculum can be influenced by the presence of an antagonistic microflora in the soil. There are suppressive soils in which some soilborne *F. oxy- sporum* causing vascular diseases reduce their activity for the presence of antagonistic bacteria present in the rhizosphere.

7. Environmental Factors. Host development is often strongly influenced by environmental conditions. Moisture and temperature are the most important factors and both may affect seed and spore germination, seedling infection, and the first steps of disease development. Common bunt of wheat requires the teliospores to germinate at the same time as the grain, being too short a period of seedling susceptibility. In this case, soil temperatures affect spore germination, and seed transmission rates of the fungi can vary considerably. Teliospores located on the seed surface germinate optimally at 10–15°C, whereas at higher temperatures (20–25°C), germination is reduced. For this reason seeds of the same seed lot used in areas of different climatic conditions produce different percentages of infected plants. Internally localized pathogens normally produce infected plants and there are no significant effects of soil environment on pathogen transmission. Sowing date or geographic crop location do not change the incidence of loose smut of wheat (*Ustilago tritici*) or other similar host–pathogen combinations. In general there are particular geographic and climatic pattern and, temperatures and humidity strongly associated with fungal, viral, and bacterial seed-transmitted diseases. The establishment of infection is favored if, after sowing, the temperatures cause a slow development of seedlings.

8. Cultural Practices. Sowing data, sowing depth, soil type, soil pH, seeding rate, and fertilizers, etc. may affect pathogens seed transmission by having some direct or indirect effects on host, pathogen, and environment. Early sowing and shallow planting of wheat, for example, cause the reduction of bunt transmission, whereas deep sowing may cause the extension of the germination period and consequently seedling susceptibility.

### CONCLUSION

Seed lots today move around the world more frequently than in the past. As a consequence, there are more opportunities for the spread of new pathogenic microorganisms in seed crops, as evidenced by the many new seedborne diseases recorded in the last ten years.

According to the practices of "Integrated Pest Management," it will be very useful in the future to increase the use of seed health tests that can forecast the amount of inoculum transmitted to plants in different climatic conditions.

Sex Chromosomes in Plants

M. Ruiz Rejón
Universidad de Granada, Granada, Spain

INTRODUCTION

Unlike the situation in the animal kingdom, most plants are hermaphrodites. In fact, only about 5% of the 250,000 species of flowering plants are dioecious, having separate females and males. In less than a dozen of these dioecious species, sex is determined by chromosomes such as the X and Y that are so well known in animals. Despite their low number, plant species with sex chromosomes enable investigations of the origin and evolution of these chromosomes, and also advance the genetic improvement of commercial plants.

THE ORIGIN AND EVOLUTION OF SEX CHROMOSOMES

Currently, the most widely accepted hypothesis on the origin of sex chromosomes is that they first arose when a pair of nondifferentiated chromosomes joined together the genes that control male and female sex (i.e., genes that inhibit the development of either female or male sex organs). Second, at some point, differentiation occurred in the zone bearing these genes, which suppressed recombination in this area. Third, suppression of recombination was extended to more areas of the sex chromosomes, followed by a degeneration of the Y chromosome and the appearance of dosage-compensation mechanisms in the X chromosome. In short, this evolutionary process appears to have proceeded in three stages (Fig. 1).

This hypothesis is based on the very old sex chromosomes of animal species, normally in the last stages of this evolutionary process. However, dioecious plants, being at different stages in the process of chromosome differentiation (Table 1), offer a unique opportunity to investigate this process.

The First Stage: Asparagus

In asparagus (Asparagus officinalis), males as well as females have 20 chromosomes (Fig. 2A), and sex is controlled by two regulatory genes—the male activator (M) and the female suppressor (F). The males are heterozygous (MF/mf) and the females homozygous (mf/mf). These genes are located in chromosome 5, which has a similar morphology in both males and females. This similarity indicates that dioecism is of very recent origin in asparagus, and that chromosome 5 can be considered as an example of an incipient sex chromosome.

The Second Stage: White Campion

In the white campion (Silene latifolia), females have 22 autosomes (chromosomes with similar morphology in males and females) and two X chromosomes, whereas males have 22 autosomes as well as one X chromosome and one Y chromosome.

The origin of the sex chromosomes in the white campion is recent (some 20 million years ago (M.Y.A.) versus some 100 million years ago in mammals). Thus, although a differentiated sex-chromosome system developed with restriction of recombination in some regions, the process has not advanced to extensive degeneration of the Y and dosage compensation of the X.

The sex chromosomes are the largest chromosomes of the karyotype, with the Y larger than the X. Pairing occurs only during meiosis in one terminal region (Fig. 2B), indicating the suppression of recombination over much of their length.

The Y chromosome became differentiated from the X chromosome in at least three interstitial regions. These regions are thought to contain regulatory genes similar to those mentioned in asparagus. The white campion, however, may have three types of regulatory genes—one gene that suppresses the development of the carpels (female flower parts), and two genes that promote the development of anthers (male flower parts, one early and one late).

At the molecular level, the gene that suppresses the development of the carpels and the gene that promotes the (late) development of anthers are distally located at the ends of the nonrecombinant region of the Y chromosome, whereas these two genes are closely linked in the X. This differential disposition may have come about through chromosome rearrangements such as inversions and/or translocations. These rearrangements have suppressed recombination between the two chromosomes, thereby avoiding breakage of the two allele combinations that determine male or female in the sex-controlling genes.
The white campion has no signs of degeneration of the Y chromosome; it is not heterochromatic (i.e., it does not show differential staining with respect to the remaining chromosomes), nor does it possess specific satellite DNA (a kind of repetitive DNA that may lack any function). In addition, although a functional gene has been found in the X chromosome for which its homologue in the Y is degenerated, two other functional genes have been found in the X chromosome for which their copies in the Y are not degenerated. The fact that some diplohaploid YY plants (plants obtained by duplication from a haploid male cell with a Y chromosome) are viable and fertile indicates that the process of degeneration of the Y has not been completed for many genes.

With respect to the appearance of dosage-compensation mechanisms in the X chromosome, the data for *S. latifolia* are not conclusive. In females, the two X chromosomes differ in replication time and appear to be differentially methylated (marked with a CH3 group in the cytosine of CG dinucleotides), but there are no signs of facultative heterochromatinization (reversible heterochromatin) in one of the two X chromosomes in the females.

The Third Stage: Sorrel

Sorrel (*Rumex acetosa*) females have 14 chromosomes, two of which (the large pair) are the X chromosomes. The males have 15 chromosomes, including 12 autosomes, one X chromosome, and two Y chromosomes of different sizes (Y1 and Y2). Y1 and Y2 are the largest chromosomes of the karyotype after the X chromosome. This composite chromosome system is believed to have arisen from a simple XX/XY by translocation between the X and an autosome, giving rise to the new X, with the primitive Y being Y1 and the homologue of the autosome being Y2.

In meiosis, the two Y’s pair with the end of each arm of the X; thus, there is no meiotic recombination between the two Y’s nor with the majority of the X (Fig. 2C). The Y’s show clear signs of degeneration, are heterochromatic (Fig. 2D), and are rich in at least two satellite-DNA families with respect to the X and the autosomes, one of these satellites being specific to the Y’s.

</table>
The X’s show no clear signs of dosage compensation. In females, there is no heteropicnosis (differential staining) of one of the X chromosomes. The genetic-control system in sorrel, however, depends on the ratio of X:autosomes (for this ratio, the females have a value equal to 1 and the males 0.5), in which the compensation, if it occurs, would lead to gene hyperactivity in the X chromosome of the males rather than to the inactivation of an X of the females.

Plants such as *R. acetosa* constitute the third stage in the evolutionary process of the origin of the sex chromosomes characteristic of many animal species. In fact, in the Y chromosomes of sorrel, in addition to the previously mentioned satellite DNA, genes also control male fertility, as is also the case in humans. In this sense, sorrel plants with an X:autosome ratio of 0.5 but without Y’s are sterile males.

CONCLUSION

Despite the facts that research on sex chromosomes in plants has lagged behind that in animals and that enigmas persist, recent accelerated investigation using molecular tools is enabling the testing of the general hypothesis for the origin of sex chromosomes. In fact, the different stages proposed by this hypothesis have been found in plants, thus confirming that sex chromosomes originated as a mechanism to avoid breakage of the two alternative combinations that give rise to males or females in sex-determining genes.

The role of the genes themselves in determining the sex of plants and whether they are located in the sex chromosomes or in the autosomes need clarification. For the moment, the genes identified in the sex chromosomes of plants (e.g., the case of the functional genes of *Silene latifolia* discussed above) do not intervene directly in the control of sex. In different dioecious species, genes involved in floral development are not associated with the sex chromosomes nor with sex control.

All these findings are of great interest from scientific and applied standpoints. In scientific terms, the analysis of dioecious plants in which the development of one of the sexes is halted will enable an understanding of the development of hermaphroditic plants in which both sexes appear. From an applied perspective, all these findings are of interest in areas of genetic plant improvement such as early determination of plant sex in crops that benefit from only one sex, in developing single-sex populations, in manipulating the reproductive systems of plants by converting them from dioecious to hermaphroditic and vice versa.
versa, and in controlling pollination for the production of hybrid seeds.

Shade Avoidance Syndrome and Its Impact on Agriculture

Garry C. Whitelam
University of Leicester, Leicester, U.K.

INTRODUCTION

The ability to acquire information about their surroundings and use this information to modify behavior or development is a characteristic of all living organisms. Being sessile organisms that are not able to choose their environment, plants need to be especially plastic in their development in order to optimize their growth in response to environmental change. Since plants depend upon light as an energy source for the process of photosynthesis, they are especially sensitive to variations in the light environment. Plants monitor a range of light signals such as intensity, quality, and direction, and use this information to modulate a wide range of developmental and physiological process ranging from seed germination, seedling establishment, shoot architecture, the onset of flowering, and fruit development. Three principal families of signal-transducing photoreceptors have been identified in higher plants: the red/far-red (R/FR) light-absorbing phytochromes and the UV-A/blue light-absorbing cryptochromes and phototropins.[1] In light-grown plants, R/FR light signals acting through the phytochromes enable plants to detect nearby vegetation and to evoke the shade avoidance syndrome of responses.

PROPERTIES OF PHYTOCHROMES

The phytochromes are biliproteins that absorb maximally in the R (600–700 nm) and FR (700–800 nm) regions of the spectrum. The phytochromes exist as a homodimer of two subunits that each consists of a polypeptide (ca. 1200 amino acids) and a linear tetrapyrrole chromophore attached via a thioether linkage to a conserved cysteine residue in the N-terminal globular domain of the protein. Light-induced interconversions between Pr and Pfr involve isomerization of the tetrapyrrole chromophore, accompanied by reversible conformational changes throughout the protein moiety. Phytochromes can exist in either of two relatively stable isoforms: a R light-absorbing form (Pr) with an absorption maximum at about 660 nm, or a FR light-absorbing form (Pfr) with an absorption maximum at about 730 nm. The Pfr form of phytochrome is generally considered to be biologically active, and Pr is considered to be inactive. The absorption spectra of Pr and Pfr show considerable overlap throughout the visible light spectrum, and so under almost all irradiation conditions phytochromes are present in an equilibrium mixture of the two forms that tends to reflect the relative proportions of R and FR wavelengths.

Higher plants contain multiple discrete phytochrome species that make up a family of closely related photoreceptors, the apoproteins of which are encoded by a small family of divergent genes. The size of the phytochrome family varies among different plant species. In dicotyledonous angiosperms, including the model species Arabidopsis thaliana, five apophytochrome encoding genes (PHYA–PHYE) have been characterized. Apophytochromes A, B, C, and E are evolutionarily divergent proteins, sharing only 46–53% sequence identity, whereas PHYD encodes an apoprotein that shares 80% sequence identity with apophytochrome B. Molecular phylogenetic analysis supports the occurrence of four major duplication events in the evolution of phytochrome genes. An initial duplication is believed to have separated PHYA and PHYC from PHYB/D/E. The subsequent separation of PHYA from PHYC and PHYB/D from PHYE resulted in three subfamilies: A/C, B/D, and E.[2]

PHYTOCHROMES AND SHADE AVOIDANCE

Phytochromes play a major role in regulating seed germination and early seedling establishment. In light-grown plants, the phytochromes mediate two principal responses: photoperiodic perception, leading to floral induction in some species, and proximity perception, leading to the shade avoidance syndrome. The shade avoidance syndrome, one of the best-studied examples of adaptive phenotypic plasticity in plants, is a suite of developmental responses initiated by the reflected/scattered light signals generated by neighboring vegetation.

The daylight spectrum has more or less equal proportions of R (600–700 nm) and FR (700–800 nm), but the selective absorption of blue and R wavelengths by the chlorophylls causes the radiation that is reflected/scattered by green leaves to be relatively enriched in the FR (Fig.1). This FR-rich light signal (i.e., a reduction in R:FR ratio) is detected by nearby plants as a change in the equilibrium between Pr and Pfr and provides a unique and
unambiguous signal that potential competitors are nearby. The magnitude of the reduction in R:FR ratio is quantitatively related to the proximity and density of the neighboring vegetation. In response to low R:FR ratio signals many plants evoke competitive reactions, including increased elongation of internodes and/or petioles, reduced leaf growth, and increased apical dominance, in an attempt to avoid being shaded. In many competitive plant species, such as arable weeds and a number of crops, internodes are especially sensitive to the low R:FR ratio signal. This correlates well with the finding that the reflected low R:FR ratio signal is particularly intense in internodes. The importance of the internode response was demonstrated in field experiments in which individual internodes of *Sinapis alba* or *Datura ferox* were screened for the low R:FR ratio signal by annular cuvettes containing copper sulphate solution, which absorbs strongly in the FR. Such “blinded” internodes failed to elongate in response to the proximity signal generated by growing plants at high densities. In some species, prolonged exposure to the low R:FR ratio signals evokes a survival reaction, the acceleration of flowering.

The roles of individual phytochromes in regulating shade avoidance responses have been largely inferred from studies of mutant plants deficient in one or more of the phytochromes. In a number of plant species, deficiency of phytochrome B has been shown to result in plants constitutively displaying phenotypes comparable to those of the shade avoidance syndrome. This indicates a major role for phytochrome B in the perception of the R:FR ratio signal. However, the retention of some sensitivity to low R:FR ratio signals in mutants that are null for phytochrome B indicated the involvement of other phytochromes in shade avoidance. Phytochromes D and E were subsequently shown to play a role in R:FR ratio perception.

### SHADE AVOIDANCE IN AGRICULTURE

When plants grow in close proximity to one another, the shade avoidance syndrome is invoked. These responses are likely to be of benefit to individual plants growing in mixed communities, by providing a means of competing for light through the reallocation of resources. In an agricultural setting, however, shade avoidance represents an undesirable trait that diverts resources into increased stem and petiole elongation to support competitive growth, and away from agriculturally important activities such as root, leaf, and seed/fruit growth. Despite the strong selection for high yield in monocultures that has characterized the breeding of modern crops, many crop plants have retained the shade avoidance response to nearby vegetation and so show increased stem elongation when grown at increasing densities.

Crop productivity is a complex function of the acquisition and distribution of resources. Shade avoidance responses lead to dramatic alterations in resource allocation that can severely limit harvestable biomass in monocultures. Thus, it can be predicted that by rendering individual plants insensitive to the low R:FR proximity signal, the wasteful allocation of resources into competitive growth should be reduced, with a concomitant increase in harvestable yield. This notion has been tested in an elegant field experiment in which a transgenic approach was used to suppress shade avoidance responses. Tobacco plants were genetically engineered to overproduce phytochrome A, a member of the phytochrome family that normally plays a major role in seedling development in response to FR signals. When overexpressed, phytochrome A antagonizes the action of phytochrome B (and presumably phytochromes D and E), so that the plants do not display increased stem elongation in response to the low R:FR ratio signal. When such plants are grown in the field at different densities, in contrast with wild-type plants, they do not show proximity-induced increases in stem elongation. In fact, they show proximity-conditioned dwarving. Significantly, the transgenic plants display increased harvest index compared with wild-type tobacco plants. It is anticipated that suppression of shade avoidance would have similar benefits in a range of crops.
CONCLUSION

By perceiving the FR-rich light signals reflected from leaves, the phytochromes enable plants to detect the presence of neighboring vegetation and to initiate competitive growth responses: the shade avoidance syndrome. Although beneficial to individuals growing in mixed communities in the competition for light, shade avoidance in many crop plants leads to a wasteful redirection of resources that reduces harvestable biomass. Experimental approaches are being developed that may lead to suppression of shade avoidance in crops, with attendant increases in yield.

Social Aspects of Sustainable Agriculture

Frederick H. Buttel

University of Wisconsin, Madison, Wisconsin, U.S.A.

INTRODUCTION

Agriculture—conventional and sustainable, “traditional” and “modern”—is intrinsically social (or sociotechnical) in nature. The social character of agriculture is particularly apparent, particularly widely recognized, and particularly crucial in the case of sustainable agriculture. Not only must any reasonable definition of sustainable agriculture include both social and economic as well as technological and ecological components, the roots of unsustainability and the pathways to sustainability are fundamentally social processes. This chapter will provide an overview of the most fundamental social dimensions of sustainable agriculture.

THE DEFINITION OF SUSTAINABLE AGRICULTURE

It is widely agreed that sustainable agriculture is intrinsically a joint social and ecological construct. Thus, for example, Ikerd[1] stresses the “anthropocentric” as well as “ecocentric” nature of agricultural sustainability, noting that the essence of sustainable agriculture is that “we [in sustainable agriculture] are concerned about sustaining agriculture for the benefit of humans, both now and into the indefinite future.” Sustainable agriculture is an agriculture that is “ecologically sound, economically viable, and socially responsible.”[2] Allen similarly emphasizes that a conception of sustainable agriculture that fails to recognize the role of people, social actors, social institutions, and social movements is a limited one.[3]

Sustainable agriculture and organic farming are very closely related but are not exactly coterminous. Organic farming systems tend to be highly sustainable systems according to the ecological and social components of the definition of sustainable agriculture, and are often quite economically viable as well.[4-5] Many in the sustainable agriculture community, however, feel strongly that sustainability improvements in mainstream or conventional agriculture are as important as the expansion of organic farming and organic agro-food systems.

STRUCTURAL CAUSES OF THE LACK OF SUSTAINABILITY

Agricultural sustainability is not only a vision of the long-term goals for agriculture, which imply measuring sticks for or indicators of its achievement.[6] Sustainability also implies a critique of or a set of concerns about “conventional” agriculture—that mainstream agriculture has shortcomings in terms of environmental soundness, economic soundness, and social justice—and suggests that there have been trends over time that jeopardize the achievement of these three ends.

The historical U.S. pattern of abundant land, limited and/or relatively expensive rural labor, and a strong tendency toward overproduction and low commodity prices has encouraged a capital-intensive, chemical-intensive monocultural system with a very high degree of enterprise and spatial homogeneity (or specialization). Commodity, trade, and public research policies have historically reinforced these tendencies to monoculture, specialization, and heavy reliance on chemicals, leading to an agriculture that has significant shortcomings on all of the criteria implied in the definition of sustainable agriculture.[7]

SUSTAINABILITY AND THE CORPORATE-INDUSTRIAL AGRICULTURAL ECONOMY

Agricultural sustainability cannot be considered apart from the globalized and highly concentrated corporate economy within which sustainable agriculture, and agriculture as a whole, is enmeshed. Corporate concentration on input provision, food processing, and retailing limit the choices available to sustainable and other farmers. Corporate control over agriculture is increasing through processes such as the disappearance of “open markets” for agricultural products; the extension of vertical integration and contractual relationships; and the ever closer alignment of multinational chemical and seed companies on one hand, and food processors, manufacturers, and global trading companies on the other.[8] There is evidence that the increased corporate domination of

Encyclopedia of Plant and Crop Science

Copyright © 2004 by Marcel Dekker, Inc. All rights reserved.
agro-food systems has negative implications for achieving agricultural sustainability. Farmer contractees, for example, are typically directed contractually by “integrators” to use particular practices which, more often than not, are unsustainable.

It should be stressed, however, that corporations—often small ones, but also large firms—have been major agents in extending the scope of organic food production and organic marketing. There are two major nationwide organic chain grocery stores, and a number of corporations have been very successful in producing organic products such as potatoes, grapes, fresh fruits and vegetables, and so on. The corporate organization of the organic food industry represents a major dilemma for proponents of agricultural sustainability. Highly successful sustainable agriculture ideas will be attractive to private corporations, which will often be successful in diffusing products and practices. At the same time, corporate agricultural sustainability practices may undermine certain aspects of the sustainability agenda (e.g., large-scale monocultural production of organic potatoes in the Northern Intermountain states is associated with a considerable threat of soil erosion and loss of biodiversity).

There is considerable debate in the sustainable agriculture community as to whether the best indicator of the growth of sustainable agriculture is the national market share of organic food—much of which is due to the activities of very large corporations such as Whole Foods—or whether the extent of sustainable agriculture is most accurately measured by the prevalence of community-supported agriculture (CSA), farmers markets, local co-ops, community gardens, and direct marketing of food. Those with the strongest commitments to sustainable agriculture are also most likely to see food system localization and the re-creation of more local “foodsheds” as the heart and soul of a genuine and enduring sustainable agriculture.

SUSTAINABILITY AS A SOCIAL MOVEMENT

Agricultural sustainability is as much a social movement as it is a set of technologies and production practices. Social definitions of sustainability—that is, the concerns, views, ideologies, and agendas of movement participants—are as or more important in shaping what sustainability is as ecological or biological indicators such as soil erosion rates, levels of soil organic matter, biodiversity, levels of runoff, and so on. What has put sustainability on the national and global agenda is primarily the organization and activities of three major types of groups: farmer-driven sustainable agriculture organizations and movements, consumer-driven or consumer-oriented sustainable agriculture initiatives (such as many CSA farms and most food co-ops and local food councils), and national and global environmental groups. Environmental groups have arguably done the most to increase the visibility and persuasiveness of the overall notion of sustainability, and of the particular concept of agricultural sustainability, though farmer-oriented groups do not always agree with environmentalists’ agendas for agricultural sustainability.

Each of the three main types of sustainable agriculture organizations, however, agrees on the main components of the movement agenda: the need for more public research on sustainable practices, the need for public policy incentives for sustainability, the desirability of family farming, and the imperative to improve the environmental performance of agriculture. Increasingly, this consensus has extended to issues such as opposition to major trade liberalization agreements (the World Trade Organization and NAFTA) and opposition to genetic engineering of crops and foods.

PUBLIC POLICY AND THE FUTURE OF AGRICULTURAL SUSTAINABILITY

Three necessary but insufficient conditions for the continued advance of sustainable agriculture are the development of improved sustainable technology; the presence of a vigorous and dynamic sustainability movement; and the development of a public policy environment that reduces the public policy disincentives to an environmentally sound, socially responsible, and economically viable agriculture. Of these three conditions, the public policy environment of agricultural sustainability is arguably the most important over the long term, even though the macro-public-policy environment is difficult to redirect, and there are areas of public policy disagreement among farmers, consumers, and environmental actors in the sustainable agriculture community. For example, some sustainability advocates, particularly those in the environmental community (and some farm groups in that community), believe that the federal (and global) levels of action are most important or efficacious, whereas others believe that at this time the local (community or regional) arena is where advocates can most easily make a difference. Nonetheless, it is apparent that over the long term sustainable agriculture cannot advance far in a public policy environment that involves the strong disincentives to sustainability that currently prevail. There is a need for more active federal, state, and local regulation of both the on-site and the off-site impacts of agriculture; for ending the commodity-driven pattern of federal agricultural policy that shoveled the lion’s share of subsidies in the direction of large, monocultural producers of overproduced commodities; and for redirection of the public
agricultural research agenda. Some of the most innovative public policy ideas in sustainable agriculture are being developed in Europe. Green payments, taxes on pesticides and fertilizers, and the embrace of a “multifunctionality” approach to government agricultural policy are particularly promising policy instruments. Each of these policy instruments would support sustainability and yield other benefits (reduced government outlays, rural development, reduced greenhouse gas emissions). Still, there are no technocratic shortcuts to sustainability. Sustainability is, and must remain, as much a social movement as it is a set of practices and measuring sticks of agro-food system performance.

Somaclonal Variation: Origins and Causes

Philip Larkin
CSIRO Plant Industry, Canberra, Australia

INTRODUCTION

Somaclonal variation is the genetic variation that is sometimes observed when plants are regenerated from cultured somatic cells, compared to the plant used as a source of the culture. Such variation represents both a problem and an opportunity. For those concerned with micropropagation of valuable elite clones, this variation can result in problematic off-types that diminish the commercial value of propagules. Likewise, genetically enhanced (transgenic) plants are carefully screened to avoid unwanted and unintended somaclonal variation, so that the commercially released clone has only the beneficial effects from the transgene. On the other hand, some somaclonal variants have proved to be of agronomic and commercial advantage and in a limited number of cases have been released as new cultivars. Various types of somaclonal mutation have been described, including point mutations, gene duplication, chromosomal rearrangements, and chromosome number changes. Transposable element movement and changes in DNA methylation have been implicated as mechanisms behind some, but not necessarily all, somaclonal variation. It may be that somatic cells, both in the plant and in culture, naturally accumulate these changes and that the tissue culture environment provides an opportunity for these mutations to be uncovered in tissue culture–derived plants.

BACKGROUND

Recognition that plants regenerated from cell culture could carry mutations began in the 1970s and was initially met with scepticism. The earliest systematic work on somaclonal variation was in sugarcane, tobacco, rice, ryegrass, lettuce and, potato.[1–4] Potato variants were observed after regeneration from cultured protoplasts; this was named protoclonal variation.[5] The more general designation ‘somaclonal variation’ was coined when it had become evident that the phenomenon could occur following all forms of culture of somatic cells.[6]

NATURE OF THE GENETIC CHANGES

Table 1 summarizes types and examples of somaclonal variation.[1]

Experiments with multiple regenerated plants from isolated single-leaf protoplasts have demonstrated that somaclonal variation sometimes occurs during the period of culture and sometimes appears to preexist in the leaf. The frequencies of occurrence of these mutations vary widely. The maize ADH (alcohol dehydrogenase) point mutation was found only once among 645 regenerants. One β-amylase mutation in wheat was found among 149 regenerants in which four loci were screened. In some experiments[7] the rate of mutation from somaclonal variation was about tenfold higher than from mutagen ethyl methanesulfonate (EMS) on seed or pollen.

ORIGINS OF THE GENETIC CHANGES

The causes (nature) of the genetic changes can be described more easily than the originating mechanisms. The trigger for somaclonal variation may not be unique to cell cultures but may occur naturally in plant somatic tissues. In other words, cell culture may simply be an effective means to uncover and reveal the genetic changes by giving opportunity for the mutated cells to become mutated plants.

It has been suggested that the causative condition for somaclonal variation is high auxin levels, rapid cell division, or return to a juvenile genomic state, but there is little persuasive evidence. Likewise, the trigger has been described as genomic shock or plasticity, which occurs after the plant has exhausted its ordinary physiological responses to environmental stress.[8] These interpretations of the sometimes massive genetic changes observed with somaclonal variation seem reasonable but do not describe the actual mechanism of unleashing the genetic plasticity.

More recently it has been shown that cell culture can cause the activation of transposable elements.[9] Excision of a transposable element leaves a double-stranded break at the donor site. The cell attempts to repair the breaks...
sometimes by strand-to-strand sister chromatid ligation. Subsequent rounds of replication initiate the so-called breakage-fusion-bridge cycle, which ceases only when new telomeres are added to the chromosome ends.

A number of researchers have observed both increases and decreases in C-methylation and A-methylation during cell culture. This phenomenon can result in altered gene expression, although the direct effects are likely to be less stable over time. However, others have described how short-term changes in methylation can result in stable point mutations. “Repeat-induced point mutation” (RIP) was first described in *Neurospora*, and may be a significant underlying cause of somaclonal variation in cultured plant cells; in the plant cell context “methylation-induced mutation” may be a more appropriate name. Newly methylated cytosines can be deaminated to form thymines, resulting in sequence mutation. It is also possible that transient changes in DNA methylation lead to bursts of transposable element movement, with consequent stable genetic changes and chromosome structural alterations, as explained above.

It is therefore difficult to envisage a single originating mechanism that can trigger all the various types of somaclonal variation. The current author therefore favours the view that there are a variety of mechanisms, most or all of which occur naturally in the somatic cells of plants and also in cultured plant cells, perhaps at a higher frequency. Plant regeneration from single somatic cells gives the opportunity to reveal these changes as solid mutant plants. In addition, cell culture itself may be sufficiently stressful to unleash the preprogrammed genomic shock, which is an adaptive mechanism that activates when ordinary physiological responses are insufficient. The occurrence of hot-spots of mutation and recurring menus of alternative alleles, described by some investigators, is consistent with this preprogrammed response.

**HOMOZYGOUS MUTATIONS**

A number of researchers have observed somaclonal variation appearing as homozygous mutations (e.g., in rice, wheat, and maize). Homozygosity might be explained in a number of ways: The mutational mechanism is not random and occurs on both homologues; the mutation is rendered homozygous by a type of gene conversion; there are cycles of haploidy (or chromosomal monoploidy) and diploidy such that a mutation on one homologue is duplicated to achieve homozygosity. Some researchers describe a type of somatic meiosis in culture that might explain the ability for mutations to become homozygous. Somaclonal variation in soybean produces alleles already known in the soybean germplasm, suggesting a type of non-random mutation giving controlled formation of alternative alleles in response to stress.

**PROBLEM FOR MICROPROPAGATION AND GENETIC MODIFICATION OF CROPS**

Almost invariably micropropagation of horticultural species (and clonally propagated crops such as banana) is intended to produce chosen elite individuals in mass. Somaclonal variation is problematic under these circumstances, where even a low percentage of off-types is unacceptable for commercial use; a high percentage can

be very costly, as has been proven in both the banana and oil palm industries.

Likewise, somaclonal variation can be problematic in the genetic modification of crops. A number of studies indicated higher levels of somaclonal variation following transformation procedures than in control populations of regenerants. Here, however, hundreds of individual transgenics are exhaustively tested and only proven elite individuals are chosen to become commercial releases. Somaclonal variation is not a great problem in species where transformation is relatively easy or where the breeding system allows backcrossing to eliminate unwanted changes. The problem is very significant in species such as sugarcane.

EXAMPLES OF SOMACLONAL MUTANTS BEING BENEFICIAL

The literature records instances of somaclonal variation in a large range of plant species, including major food crop species wheat, barley, sugarcane, rice, maize, potato, tomato, soybean, and oilseed rape. The potential improvements reported include enhanced resistance to fungal, bacterial, and viral diseases, improved insect and nematode resistance, enhanced economic yield, improved drought, chilling, salinity, and aluminium tolerance. In a limited number of cases there have been new varieties and cultivars named and released commercially. Examples are listed in Table 2.

SPECIFIC EXPLOITATION OF CHROMOSOMAL CHANGES

Somaclonal variation involving subchromosomal recombination has been exploited to achieve the introgression into wheat of a particular segment of an alien grass chromosome with Barley Yellow Dwarf Virus (BYDV) resistance. In this case it was possible to introduce the whole chromosome by backcrossing the wide hybrid between wheat and Thinopyrum intermedium. This alien chromosome neither pairs nor recombines with the wheat chromosomes. However, cells from the monosomic alien addition line (all 42 wheat chromosomes and one from the grass) were cultured, plants regenerated, and progeny families screened for recombination. Five of about 1000 families (0.5%) had a recombination in which a portion of the alien chromosome, carrying the BYDV resistance, had been translocated onto a wheat chromosome. Two new Australian wheat cultivars (cvs. Mackellar and Glover) have just been released with two of these translocations.

CONCLUSION

It was thought for some time that regeneration by somatic embryogenesis might render some protection from somaclonal variation, but this appears not to be the case. Reducing the length of time in culture does seem to reduce the likelihood of gross chromosomal variation but not necessarily the less obvious and fine structural changes. If it is true that cell culture merely enables the recovery of naturally occurring somatic mutations, then it seems unlikely that somaclonal variation can be entirely avoided whenever plants are regenerated from individual somatic cells. If, however, the underlying cause is a stress that triggers changes associated with genomic trauma, then some types of culture may be found to be less traumatic. A recent study in rice indicates that while no form of culture entirely eliminates somaclonal variation, protoplast culture nevertheless results in a much higher incidence. Some vigilence will therefore continue to be required in the selection of transgenic events for commercial release.

Somatic Cell Genetics of Banana

D. K. Becker
Queensland University of Technology, Brisbane, Queensland, Australia

M. K. Smith
Queensland Department of Primary Industries, Queensland, Australia

INTRODUCTION

Bananas and plantains (Musa spp.) are grown throughout the humid tropics and subtropics, where they are of great importance both as subsistence crops and as sources of domestic and international trade. They are monocotyledonous perennial herbs consisting of sympodial rhizomes and large pseudostems composed of tightly clasping leaf sheaths, slightly swollen at the base. Suckers are freely produced. Bracts and flowers are inserted independently on a peduncle and are usually deciduous by abscission, except for functional female ovaries in the basal hands. Basal flowers are generally female with male flowers on distal hands.

Edible, seedless banana, plantain cultivars are derived from intra- and interspecific hybridisation of the two seeded, wild diploid species, Musa acuminata (A genome) and Musa balbisiana (B genome). The haploid genome of both M. acuminata and M. balbisiana consist of 11 chromosomes, but the acuminata genome has been estimated as being slightly larger, 610 Mbp cf. 560 Mbp for balbisiana. Many edible hybrids are parthenocarpic, female sterile and triploid with the relative contribution of each species to the genome being annotated by either A or B. Dessert bananas are usually AAA, plantains AAB and cooking bananas ABB.

Banana breeding programs have largely focused on generating pest and disease resistant cultivars while at the same time retaining acceptable yield and fruit quality. The two major diseases of banana are Sigatoka leaf spots Mycosphaerella spp.) and Fusarium wilt (Fusarium oxysporum f. sp. cubense). Due to infertility, triploidy and long generation time, very few conventionally bred cultivars have reached commercial release. As a result, a great amount of effort has been directed towards improving banana through the manipulation of somatic cells.

SOMACLONAL VARIATION AND MUTATION INDUCTION

Banana has benefited greatly from in vitro-induced mutation. This is largely due to the resources directed towards this approach in view of difficulties associated with breeding triploid cultivars. Genetic variation can arise as a result of the tissue culture process or be intentionally induced by the use of physical and chemical mutagens. All three approaches have been applied to banana.[1,2]

Banana plants regenerated from in vitro culture sometimes exhibit morphological and biochemical variation due to genetic changes, which is of serious concern for clonal micropropagation. These genetic changes, nonetheless, may be exploited as a source of genetic variation for banana improvement. Somaclonal variation in banana usually leads to undesirable characteristics. However, there are several examples of somaclonal variants with advantageous characteristics, some of which have been released commercially. Variants identified include Tai-Chiao No 1 (AAA), TC1-299 (AAA) and Mutiara (AAB) with Fusarium resistance, a variant of SH 3436 (AAAA) with greater resistance to Sigatoka diseases, JD Special (AAA) with larger fruit, and higher yielding variants of Agbagba (AAB).

Of the physical mutagens used in banana and plantain improvement, gamma rays have been most commonly used. Differences in radiosensitivity have been observed among different genotypes and ploidy levels. In one study,[3] the LD50 was 20–25 Gy for diploid (AA), 30–35 Gy for triploid (AAA), and 35–40 Gy for the tetraploid (AAAA). Plantain and cooking clones (AAB, ABB) had a radiosensitivity of 25–35 Gy. Among a population of plants that had regenerated from a 60 Gy irradiated explant of ‘‘Grande Naine’’ (AAA), an early-flowering plant was identified. The clone was extensively field tested, released as ‘‘Novaria,’’ and entered into commercial production in Malaysia in 1993.

Ethyl methanesulphonate (EMS) has been widely used as a chemical mutagen in banana and has resulted, at least at an experimental level, in the generation of clones with increased Fusarium tolerance.[4] The concentration required is dependent on exposure time and whether a carrier is used. EMS has been shown to be effective at 8–16 mM with an exposure of 4–5 days and also at 200 mM with a much shorter exposure of 30 min. Dimethylsulphoxide (DMSO) has been used as a carrier agent as...
it facilitates greater uptake of EMS. Other mutagens such as sodium azide and diethylsulphate have also been shown to be effective in inducing variation from banana shoot apices.

Chemical methods have also been used to manipulate ploidy in Musa, with a view to incorporating the material into conventional breeding programs. By breeding and selecting elite diploid clones, and using them to generate autotetraploids and to cross with diploids, triploid bananas could be resynthesised. Tetraploidy has been readily induced with colchicine in M. acuminata and M. balbisiana seedlings and also in vitro shoot tips. The in vitro technique has the advantage of rapid multiplication and ease of distribution of new clones for evaluation and breeding.[5] Of importance is the number of in vitro multiplication cycles, usually more than three, following colchicine treatment in order to reduce chimerism. Treatment of shoot cultures with oryzalin has also been effective in producing high frequencies of tetraploids in banana.

SOMATIC EMBRYOGENESIS AND ORGANOGENESIS

Most reports of banana regeneration have been via embryogenic cell suspensions (ECSs). Potential uses of such cultures include micropropagation, as a source of regenerable protoplasts and for genetic transformation. There is also the potential for use as a source of cells for mutagenesis, although, to date, there have been no reports of this application. Banana somatic embryos are thought to be unicellular in origin and therefore offer the potential of generating nonchimeric plants from genetically altered cells.

ECSs have been generated using a range of explants including rhizome tissue, leaf bases, immature zygotic embryos, meristems, and immature male and female flowers. Currently, ECSs are most commonly derived from immature flowers or meristems.[6,7] Both these techniques appear to be applicable to a wide range of genotypes including diploids (AA, AB), triploids (AAA, AAB, ABB) and tetraploids (AAAB). ECSs contain a heterogeneous mix of cell types and their regenerative capacity depends on the proportion of cell types. Single isolated cells and large cell clumps (200 μm to 2 mm) in general do not give rise to somatic embryos, whereas small cell aggregates (50 to 100 μm), consisting of small cells with dense cytoplasmic readily form somatic embryos.[8]

The ECSs from immature male flowers entail dissecting out clusters (hands) of immature flowers that are close to the apical meristem of the inflorescence and placing them on induction medium where they remain without subculture until embryogenic complexes appear. Embryogenic complexes are then transferred to liquid medium where a suspension of cells forms. Regeneration involves plating suspension cells on embryo development/maturation medium. Very large numbers of somatic embryos can be generated from these cells with as many as $3.7 \times 10^5$ embryos formed per 1 mL Packed Cell Volume (PCV) being reported.[6] When embryos are transferred to germination medium, the germination rate varies depending on their maturity. Leaving embryos on embryo formation/maturation medium for long periods (up to four months) results in a germination rate of over 80%.

To generate ECSs from meristems, highly proliferating clumps of meristems are induced by placing in vitro shoot cultures on multiplication medium that, depending on the cultivar, contains varying concentrations of BAP. Over a series of subcultures on this medium, primordia gradually stop forming leaves and meristems enlarge, resulting in large white meristematic nodules. Following the formation of meristematic clumps, the upper 4–6 mm of these structures (termed ‘‘scalps’’) are used as explants for induction of embryogenesis followed by initiation of ECSs in a manner similar to that of flower-derived cultures.[7] Recent work suggests that ‘‘scalps’’ are not required, but rather ECSs can be generated directly from longitudinal sections of conventional shoot tip cultures.[9]

In the only reported field trial of plants derived from ECSs, measurements were taken for the growth characteristics of 500 ‘‘Grand Nain’’ (AAA) plants regenerated from flower-derived ECS.[10] Overall, there were no significant differences in growth characteristics. The frequency of off-types for ECS-derived plants was nil, while the frequency for those derived from micropropagation was between 1.8% and 3.3% depending on the accession. This study suggests that plants regenerated from ECSs may not be any more prone to somaclonal variation than plants derived from shoot-tip culture.

PROTOPLAST ISOLATION AND CULTURE

Somatic hybridization of bananas is possible and has potential to assist the breeding of edible bananas. In a similar manner to manipulation of ploidy with chemicals, tetraploids could be generated via protoplast fusion and triploids resynthesised by crossing with diploids. Allotetraploids created by the somatic hybridization of two elite diploid clones would be very different from autotetraploids produced by chromosome doubling. As there are now a number of examples of plant regeneration from protoplasts, fusion is now a technique that can potentially contribute to banana-breeding programs. Genotypes for which plants have been regenerated from protoplasts include breeding diploids (AA), dessert bananas (AAA), plantains (AAB), and cooking banana (ABB).[11] All reports of successful plant regeneration have two factors in common. Firstly, protoplasts were derived from ECSs and
secondly, feeder cells and/or protoplast culture at high densities was required.

**GENETIC TRANSFORMATION**

As this article is concerned with genetic manipulation of somatic cells, a brief mention should be made of genetic transformation. Both meristems and embryogenic cells have been targeted for transformation; however, due to greater efficiency and the greatly reduced risk of chimerism, embryogenic cells are the tissue of choice. Following the development of efficient regeneration systems for various cultivars, transformation systems using both microprojectile bombardment\cite{12} and Agrobacterium-mediated transformation\cite{9} of embryogenic cultures have been developed. Reports of transformation to date have focussed on the development of the technique itself and the examination of the strength and tissue specificity of various promoter elements. Work in this area has now moved on to conferring useful new traits including disease resistance and altered fruit characteristics. Indeed, potentially disease-resistant transgenic banana are currently undergoing glasshouse and field trials, and delayed fruit ripening using sense suppression of genes involved in ethylene biosynthesis has been reported.

**CONCLUSION**

The difficulties associated with conventional breeding of banana have been the driving force behind the genetic manipulation of somatic cells. In some cases, such as mutation breeding, new cultivars are already in commercial production. Other techniques, such as ploidy manipulation and protoplast fusion may provide assistance to conventional breeding or be utilised independently to generate new cultivars. Although at times some controversy is associated with genetic transformation, it does provide the potential to circumvent fertility problems and allow the transfer of genes within the banana gene pool or indeed introduce genes from completely unrelated organisms. The possibilities for banana improvement have entered a new and exciting phase based on our understanding of somatic cell genetics.

Somatic Embryogenesis in Plants

Ray J. Rose
The University of Newcastle, Callaghan, Australia

INTRODUCTION

Somatic embryogenesis refers to the remarkable ability of nonzygotic plant cells (including haploid cells) to develop through characteristic embryological stages into an embryo capable of developing into a mature plant. Somatic embryogenesis is an expression of totipotency and the associated differential gene expression.

Somatic embryos may be produced in nature in certain plant species as a form of apomixis known as adventitious embryony. Somatic embryogenesis in plants usually refers to the induction of somatic embryos in vitro, first demonstrated by both Steward and Reinert in 1958. Research into somatic embryogenesis has intensified as plant regeneration in vitro has come to be widely utilized in transformation and somatic hybridization.

This article emphasizes basic procedures and key variables for inducing somatic embryos, their developmental biology, and their mechanism of induction. Somatic embryogenesis may be direct or indirect. Direct somatic embryogenesis does not require a callus phase to induce somatic embryos from the explant. Indirect somatic embryogenesis has been most extensively studied and is widely used in transformation and somatic hybridization.

PRODUCING SOMATIC EMBRYOS—THE BASIC PROCEDURE

Steward was able to produce embryos from phloem tissue explants from carrot storage roots; Halperin[1] was able to show that auxin is essential for inducing embryos and that subsequent auxin withdrawal or lowering of auxin concentration is required for embryo maturation. Based on Dudits,[2] the basic paradigm is:

\[
\text{Explant} + \text{auxin} + \text{basal medium} \downarrow \text{Callus} \downarrow \text{Embyrogenic cells} \downarrow \text{Auxin reduction or removal} \downarrow \text{Bipolar embryo} \downarrow \text{Mature plant}
\]

In leguminous plants the first success was with *Medicago sativa* where calli (produced using an auxin + cytokinin) were induced to form embryos with a pulse of high 2,4-D;[2] and in Poaceae, immature embryos cultured in the presence of 2,4-D led to the induction of embryogenic calli from which plants could be regenerated when levels of 2,4-D were greatly reduced.[3,4] There are differences in these examples in the initial explant, the timing of auxin treatments, and the use of special cultivars. The auxin paradigm from carrots has had to evolve; a discussion of the parameters to consider in producing somatic embryos in a given species follows.

PRODUCING SOMATIC EMBRYOS—KEY VARIABLES

Cultivar Selection and Genotype

Within a species, certain cultivars are more amenable to plant regeneration via somatic embryogenesis, reflecting a strong genotypic component in the ability to form somatic embryos. In *M. sativa*, Bingham and co-workers produced Regen S using recurrent selection, and two genes have been invoked in breeding for somatic embryogenesis.[5,6] In *Medicago truncatula*, highly embryogenic plants can be obtained after a single cycle of tissue culture followed by selection.[6] Whether this has an epigenetic or genetic basis is unclear. Plant regeneration via somatic embryogenesis has been achieved in numerous species (Fig. 1)—dicotyledons and monocotyledons, woody and herbaceous species, annuals and perennials.[3,7,8]

Explant Type

The type of explant is a key variable in successful somatic embryogenesis. Immature embryos have been an important source of explants in obtaining somatic embryogenesis in such difficult species as wheat and soybean.[3,4] This is consistent with the idea that immature tissues are less likely to have suffered irreversible somatic genetic change. Explant type is less important in genotypes that are strongly embryogenic (e.g., in *M. sativa* Regen S and *M. truncatula*, 2HA explants from fully expanded leaves...
are fine), whereas in more recalcitrant legumes, immature tissues from embryos are necessary. [3,5,6]

**Hormone Requirements**

The hormonal regulation of any plant process is physiologically-, developmentally-, and species-dependent so it is not surprising that the auxin paradigm must be qualified. A cytokinin plus auxin may be essential for somatic embryogenesis,[6] or cytokinin may augment the auxin response.[2] In the case of alfalfa, an auxin plus cytokinin induces callus formation, and then a high 2,4-D pulse induces somatic embryos.[5]

Abscisic acid (ABA) also plays a role in somatic embryogenesis. Initially it appeared that the role of ABA was to mimic the in vivo effect where it is part of controlled desiccation during seed formation; it was thought to lead to improvement in embryo quality. ABA studies overall indicate that it stimulates auxin-induced somatic embryogenesis. In some cases, exogenous ABA alone can stimulate direct somatic embryogenesis.[9] This recent work suggests that the role of ABA may reflect its involvement in stress responses, which are known to be capable of inducing somatic embryogenesis.[9]

**Nutrition**

Nutrition plays an important role in optimizing somatic embryogenesis; a few widely used standardized basal media have been developed.[7] The form of nitrogen is an important variable—reduced nitrogen in addition to nitrate enhances embryo initiation and maturation.[7]

**DEVELOPMENTAL BIOLOGY OF SOMATIC EMBRYOGENESIS**

Histological studies suggest that the precursors of somatic embryos are frequently provascular cells. In these cells...
near the vascular tissue, endogenous substances in the phloem may be significant. Epidermal cells may also be sites of somatic embryo precursor cells in direct somatic embryogenesis.\[9\] In direct somatic embryogenesis, the precursor cells are already embryogenically determined, whereas in indirect somatic embryogenesis, determination has to be induced. In direct somatic embryogenesis a single cell serves as the embryo precursor, whereas in indirect somatic embryogenesis, single cells can be precursors,\[10\] although this is not unequivocal\[8\] and must be established by cell tracking studies.

Once somatic embryos are formed by direct or indirect somatic embryogenesis, it is common for secondary cycles of somatic embryogenesis to be initiated, suggesting that embryogenicity has been selected for in some way, similar to the increased embryogenicity of regenerated plants in *Medicago truncatula*\[6\]. The development of the mature somatic embryo proceeds through stages similar to their zygotic counterparts (Ref. 3, Fig. 1).

**THE MECHANISM OF INDUCTION OF SOMATIC EMBRYOGENESIS**

An understanding of the induction of somatic embryogenesis requires a number of fundamental effects to be considered, including the consequences of the wounding effect when tissue is excised, hormonal influences, and how the genetic program is reset or redetermined to induce the sequential expression of embryogenic genes (see accompanying flow diagram). Broadly speaking, we can assume that most of the somatic embryo development genes will be similar to in vivo embryogenesis, and that it is the induction of somatic embryogenesis that is special.

Explant (wound stress) + hormone(s) ↓ Redetermination ↓ Early embryo genes

**Hormone Action and Stress Influences**

Hormones are the key regulators in inducing embryogenic cells. Although progress has been made in understanding basic hormone action, understanding is required in the context of somatic embryogenesis and in relation to genes such as somatic embryo receptor kinase (*SERK*). In *Daucus carota*, it has clearly been illustrated that stress can both induce and stimulate somatic embryogenesis, and in some studies stress has been related to the production of ABA.\[9\]

**Redetermining the Genetic Program**

There is clearly a complex of signalling pathways to be unravelled to link the earliest hormone- and stress-induced changes to chromosome remodelling and transcriptional activation. Chromatin remodelling involving changes in methylation may be one of the earliest changes.\[3\]

**Early Embryo Development Genes**

An understanding of somatic embryogenesis induction requires that the earliest genes in the embryo pathway be identified. The most substantive work has been carried out on the *SERK* gene, which has been shown to be a marker of embryogenic cells in *Daucus carota*, *Dactylis*, and *Arabidopsis*.\[10\] An important result has been the demonstration that transformation of the *SERK* gene into *Arabidopsis* can increase somatic embryogenesis.\[10\] The ligand for this receptor and the substrate for serine-threonine kinase activity is as yet unknown. *SERK* expression initiated in cells destined to become embryos continues until the globular stage, and is also part of normal sexual embryogenesis.

**CONCLUSION**

Somatic embryogenesis is a characteristic of flowering plants that can be unlocked in most species by defined in vitro culture of a suitable genotype, explant, and appropriate hormone regulatory signals. Although auxin is a key variable, there are repertoires of strategies that require testing in order to obtain a suitable protocol for somatic embryogenesis in a given species. Understanding the mechanism requires more fundamental knowledge of the genetic regulation of cellular dedifferentiation and differentiation.

Soy Wood Adhesives for Agro-Based Composites

Monlin Kuo
Deland J. Myers, Sr.
Iowa State University, Ames, Iowa, U.S.A.

INTRODUCTION

Before the advent of synthetic thermosetting adhesives in the 1950s, soybean, blood, and casein glues were the major adhesives for production of plywood and other glued wood products. Uncertainty regarding future supplies of petroleum-derived chemicals and stringent regulations on toxic emissions from building materials bonded with certain synthetic resins has compelled the industry to reevaluate wood adhesives from renewable resources. Rapid progress during the past 10 years in the development of soybean-based wood adhesives will be emphasized. The use of agricultural residues for panel products also will be discussed.

HISTORICAL PERSPECTIVES

Soybean-based adhesives were developed in 1928 for Douglas fir plywood production in the U.S. Pacific Northwest.[1] In the original formulation, partially defatted (extruded and expended) soy meal or flour was mixed with water and dispersed (denatured) with sodium hydroxide. Later formulations also included the use of defatted (solvent-extracted) soy flour and chemicals such as carbon disulfide, hydrated lime, and sodium silicate to impart a better water resistance to the adhesive bonds, and a small amount of preservatives to prevent mold growth.[2] Soy protein, about 50 to 55% in soy flour, is the active bonding agent. Carbohydrates (over 30%) in soy flour provide useful consistency properties for the glue but contribute little adhesion. Soy protein isolates also were used to formulate wood adhesives, but they did not offer enough advantages over soy flour to offset the cost. Annual consumption of soy meal or flour for plywood in North America was about 60 million pounds in 1940 and reached a peak of 100 million pounds in 1950.[2]

Soybean plywood adhesives typically contained 20% soy flour and 10% chemical solids in water and had high pH and viscosity. The plywood’s assemblies were either cold- or hot-pressed for up to 9 minutes, but it would take several hours to set the adhesive bonds completely. The plywood adhesives bond strength was adequate, but the adhesive bond had very poor moisture resistance. Petroleum-based thermosetting adhesives, mainly urea-formaldehyde (UF) and phenol-formaldehyde (PF) resins, because of their low costs, short hot-press time for a high production rate, and water-resistant adhesive bonds, quickly replaced soybean and other protein glues after World War II. In 1999 North America consumed 4.2 billion pounds of UF for interior plywood, particleboard, and fiberboard and 2.99 billion pounds of PF for exterior plywood and oriented strand board (OSB), as well as 195 million pounds of isocyanate resins for OSB and agro-based particleboard.[3] Very little proteinaceous wood adhesive is being used today by the wood industry.

CURRENT RESEARCH AND CHALLENGES

Soy-Based Adhesives

Carbohydrates and proteins are the most abundant renewable substances suitable for use as wood adhesives. It is a significant challenge to develop adhesives from these natural substances at reasonable costs to compete with synthetic thermosetting adhesives and to meet stringent performance requirements. The current concept to achieve this goal is to use these natural substances as copolymers with synthetic polymers to reduce the dependency on petroleum-derived chemicals. In this respect, proteins are more suitable than carbohydrates because amino, carboxyl, aliphatic and aromatic hydroxyl, and other functional groups in proteins provide abundant functionality for chemical cross-linking. Research of protein-based adhesives during the past 10 years has been made mainly with soy protein, primarily because of its availability and low cost.

Roland Kreibich (Weyerhaeuser scientist, retired) invented a cold-setting adhesive for finger-jointed lumber containing equal parts of soy protein isolate and phenol-resorcinol-formaldehyde (PRF) resin. In this lumber finger-jointing system, a soy isolate hydrolyzate and a PRF resin are separately applied onto different lumber fingers. Upon joining the two fingers a gel is formed immediately from the cross-linking between soy protein and PRF, and the adhesive bond is cured at the ambient temperature without further application of pressure. This
invention has not been published, but the adhesive is being produced and sold by a chemical company in Oregon. A U.S. patent[4] describes methods of preparing a soybean-based molding compound for rigid biocomposite materials. This soybean-based powder resin was formulated by cross-linking soy flour with 12% methyl diphenyl isocyanate (MDI). The powder resin was mixed with recycled paper fiber in a ratio of 4 parts resin to 6 parts fiber to produce molded composite products. More recently, a PF-cross-linked soy resin composed of 70% defatted soy flour and 30% of a PF cross-linking agent was developed at Iowa State University.[5] This light-colored soy resin can be used as a liquid resin for exterior grade plywood or as a powder resin for molded products, but it is not adequate as a spray resin for OSB and fiberboard. Subsequent research at Iowa State University resulted in an adhesive resin containing 70% soy flour hydrolyzate and 30% PF that could be used as a spray resin for OSB and fiberboard production.[6] A similar PF-cross-linked soy resin composed of 30% soy flour hydrolyzate and 70% PF has been developed for OSB production.[7] About 3.5% spray-dried animal blood is used as a forming agent in plywood glues for foam extrusion application. Research at the USDA’s National Center for Agricultural Utilization Research has shown that soy protein has desirable mixing and foaming properties for plywood glue foam extrusion.[8] The potential to replace blood with soy protein in plywood glue formulation would significantly reduce plywood production cost because soy flour is cheaper than spray-dried animal blood ($0.22/lb vs. $0.40/lb).

Research on the use of soybean for wood adhesives during the past decade has resulted in the commercialization of the soy isolate/PRF lumber finger jointing system and the MDI-cross-linked soy flour as a compression-molding compound. Development of the PF-cross-linked soy resins and the use of soy flour as a foaming agent in the plywood glues discussed above also are at a stage very close to being commercialized.

**Agricultural Fibers**

Growing concerns in the United States over the environment have led to changes of forest management practices, resulting in a significant reduction in wood harvest in the midst of a growing demand for wood fiber. The use of agrofibers for pulp and composite materials is commonplace in many parts of the world where there is a lack of forest resources. There is clearly potential in North America to use underutilized agrofibers for industrial purposes, and since 1995 there has been a proliferation of new manufacturing facilities in North America to produce particleboard from wheat straw.[9] The surfaces of crop plant parts are lined with an inert cuticle layer that is very difficult to bond with UF and PF resins, but it can be effectively bonded with more expensive isocyanate resins. However, the straw particleboard industry is experiencing difficulties in the use of isocyanate resins, including high resin cost, lack of tack for mat integrity, and the difficulty of releasing boards from hot presses.

Research at Iowa State University favors the use of agrofibers for the production of fiberboard instead of particleboard. The basic assumption is that the specific cuticle surface area can be very much reduced by refining crop residue (e.g., thermomechanical pulping) into pulp so that the resulting fiber furnish can be bonded with UF, PF, or soybean-based resins to produce fiberboard. It has been shown that cornstalk and switchgrass fibers are inferior to wood fiber for fiberboard, but satisfactory medium-density fiberboard (MDF) and high-density fiberboard (hardboard) bonded with UF, PF, and soybean-based resins could be made by mixing equal parts of either cornstalk or switchgrass fiber with wood fiber.[10]

**FUTURE PROSPECTS**

The wood products industry in the past 50 years has almost totally depended on petrochemicals for manufacturing wood-based composite products. Since the oil embargo of the mid-1970s, there has been a constant threat of worldwide oil shortage. Therefore, the wood products industry strongly favors research into renewable materials for wood adhesives, and the agricultural industry also is eager to invest in researching such industrial uses to expand their markets. The prices of wood adhesive raw materials fluctuate, but the order of their costs has not changed much in the past 20 years. It ranges from less than $0.10/lb for urea, followed by soy flour, phenol, blood, melamine, and isocyanates (e.g., MDI), to more than $1.5/lb for resorcinol. The current price of soy flour is about $0.15/lb, compared to just under $0.30/lb for petroleum-derived phenol. Soybean clearly has an advantage over phenol, not only in price but also for its stable future supply. Recently developed soybean-based adhesives may not be fully competitive in performance with synthetic adhesives, but they can be implemented if circumstances require.

Agricultural residue has been an important raw material for pulp and composite panel production in China. Agrofibers also are becoming important raw materials for the same purposes in other regions of the world that are poor in forest resources. The agro-based panel industry in North America has just begun. Based on available volumes of agricultural residues, the North American agro-based panel industry could potentially grow to a size about two-thirds as large as the present wood-based panel industry.[9]

INTRODUCTION

Crop productivity is regulated by complex interactions among multiple factors that affect plant growth and development. Historically, research has overcome limitations to inherent plant productivity by altering a crop through breeding and genetics, by direct alteration of a crop during its life cycle (bioregulation, pruning), or by altering the growing environment through managed inputs. Scientific advances in these pathways have produced large increases in plant productivity during the 20th century, although there remain considerable differences in crop performance from place to place and from year to year. Variability in crop productivity commonly exists because many of the factors regulating plant performance—soils, weather, pests, and diseases—vary continuously in space and time.

DISCUSSION

Scientists and farmers have made attempts to account for and control the effects of spatio-temporal variation in crop production; however, the tools to effectively deal with this source of variability have lagged behind other advances in plant and crop science. With a suite of technologies and principles composing what is commonly termed precision agriculture,[1] quantifying and managing for spatial variability in crop production is possible at increasingly smaller scales of resolution. The combination of technologies including global position systems (GPS), sensors, controllers, radios, and high-speed computers makes the acquisition, storage, and use of spatial data possible at extraordinary levels of spatial and temporal detail. However, the value of spatial data would be limited without equally impressive tools to manage and analyze these data and subsequently communicate their meaning to users in a variety of formats.

Two tools of great significance in this regard have evolved over the last few decades. These are geographic information systems (GIS), whose roots date back to the 1960s when cartographers first began to adopt computer techniques in mapmaking,[2] and geostatistics, first developed for the mining industry, also in the 1960s.[3] Briefly, a GIS provides a set of tools for collecting, storing, retrieving, transforming, and displaying spatial data for a particular set of purposes,[2] while geostatistics provides a set of tools aimed at understanding and modeling spatial variability.[4] Currently, geostatistics is to some extent offered as an integral part of a GIS but commonly, geostatistical analyses are often performed in an external software application dedicated to geostatistics and the resultant data or functions imported into a GIS.

GEOGRAPHIC INFORMATION SYSTEMS

A GIS allows you to visualize agricultural data. Nearly all agricultural data have some form of spatial component, and a GIS allows you to visualize spatially referenced tabular data in meaningful maps—data that otherwise are very difficult to interpret. The GIS represents agricultural data using geographic coordinates, which serve as the foundation for GIS software. GIS software platforms range from field GIS to desktop GIS, to Internet-enabled GIS, to the popular RDBMS (relational database management system) extended with GIS. These scalable GIS platforms operate independently or integrate together for the enterprise. The common geographical coordinate space of agricultural data is a powerful feature of the GIS that lets users from multiple disciplines manage a project and collaboratively share their work. A farmer, an agronomist, and an agricultural economist can all assess a crop condition and evaluate it using their own professional practices, which are applied through the GIS. Specialized features in the GIS serve to document each sequential
spatial operator and process used. This allows different users to compare and share their spatial analyses and results for optimum decision making.

An agricultural landscape is made up of many interconnected spatial components; a GIS is used to model and analyze this complexity. Georeferenced map layers can include hydrological features, soil characteristics, slope and its derivatives, yield, pests, and anything relevant to a particular investigation. The functionality to extract and highlight certain data features from one layer of information by defining a data feature from a second layer is a powerful analytic tool. Spatial operations are available, like distance buffers that allow the determination of boundaries around a location such as a creek. Some features—an irrigation well, for example—have many associated attributes that cannot be defined as a simple location. Knowledge about a well’s depth, the salinity of its water, and the time required for an aquifer to recharge it are some of the data attributes that can be evaluated with a GIS.

A field GIS provides the ability to look at images and maps of fields while actually standing in them. Editing capabilities provide the functionality to map a measurement or observation such as those encountered in crop-scouting activities. Users are able to collect in the field whatever information is relevant to them and record it directly using the map to provide the geographic location. The data highlighted and recorded in the field GIS map can be transferred to other GIS platforms, such as an Internet GIS server, or to a desktop GIS.

Desktop GIS software provides tools to carry out more intensive computational procedures such as those made using satellite images or aerial photographs. Images are generally raster based, being made of discrete cells with numeric values. Data layers that are made up of points, lines, and polygons are referred to as vector data. Raster data can be combined with vector data, but require different tools for management and interpretation. Remote sensing/GIS applications include estimating crop vigor, the remote estimation of areas in a field that are under physiological stress, and the documentation of natural resource conditions, such as soil erosion extent.

A GIS is well suited to address significant social and economic issues related to agriculture, although the mechanics of engineering a GIS solution from the farm field to the grocery store shelf can be complex. For example, the geodatabase underlying a GIS can be engineered for the application development of intelligent polygonal objects that can spatially account for transactions in the food supply chain for identity preserve (IP) requirements. This type of GIS implementation is able to record every transaction on every parcel, warehousing metadata and other critical data required for future certification of genetically modified organism (GMO) compliance regulations.

GEOSTATISTICS

Although spatial data are essential to GIS, they are sometimes too expensive or difficult to obtain. Fortunately, techniques are available to model spatial variability based on limited sampling from which estimates of spatial data can be obtained. These so-called geostatistical techniques rely on the concept of spatial continuity (i.e., the notion that two attributes close to each other are more likely to have similar values than are two that are far apart).

The scientific methods used to collect, summarize, analyze, and interpret empirical data that are referenced geographically are assembled under the heading of spatial statistics. The three main components of spatial statistics are distinguished through the data structures as methods applicable to lattice, point pattern, and geostatistical data. A geostatistical data set consists of measurements or classifications of one or more attributes of interest, along with the geographic coordinates at which the observations were obtained throughout a continuous domain.

Statistical methods appeal to a random mechanism in order to separate sources of variation. Consider, for example, the sampling of crop yield on a field at 50 randomly chosen locations. The geostatistical method appeals to a random mechanism that generates the entire (continuous) crop yield surface (a random field). The 50 samples represent an incomplete observation of a randomly generated, continuous surface. It is of interest to reconstruct the surface by predicting the yield values at unsampled locations (i.e., to produce a continuous map of crop yields). Worth noting is that a second realization—in the statistical sense—of the random process would lead to a different crop yield surface.

The prediction task is accomplished by methods of kriging. The term “kriging” was coined by Matheron in recognition of mining engineer D.G. Krige. Although kriging is often considered an optimal method of spatial prediction, the classical kriging predictors are best only in the sense of minimizing the mean square prediction error in the class of predictors that are unbiased and linear functions of the observed data.

Computation of the kriging predictor requires: 1) knowledge (simple kriging) or a model of the large-scale trend (constant mean: ordinary kriging; linear mean function: universal kriging), and 2) the ability to evaluate the autocovariance between attributes at spatial locations. In practice, the large-scale trend and the spatial covariance structure are usually subject to estimation. Because estimating the autocovariance or semivariance (one-half the variance of the difference between two attributes) is usually not possible without some form of stationarity assumption (the expected value is constant and does not depend on position), it is important to remove large-scale trends in the data prior to estimating covariances or the semivariogram to
prevent these representations of the second-order structure from depicting spurious spatial dependencies. Alternatively, methods that estimate large-scale trend and spatial correlation structure simultaneously can be employed. Likelihood methods belong to this latter class and have recently gained much momentum. Even for stationary processes, the fact that process parameters are estimated is typically not reflected in measures of prediction error. Estimates of the prediction error that consider estimates of semivariogram (covariogram) parameters as fixed quantities tend to overestimate the precision of kriged maps.

Through the years, a large number of kriging variants were developed to cope with the varied situations in which predictions of random attributes are needed. We mention by name only a few: block-kriging, indicator kriging, probability kriging, trans-Gaussian kriging, log-normal kriging, cokriging, and disjunctive kriging. For details on the various kriging methods and their implementation consult, for example, Journel and Huijbregts, Cressie, [5] Chilès and Delfiner, [7] and Schabenberger and Pierce. [8] The basic premise of these variations is the same: to obtain predictions that are best based on the second-order properties of the process under study.

It has been questioned whether the rapid increase in the complexity of scientific questions can be met by current or new geostatistical concepts based on these classical ideas. In particular, as the temporal component in spatial data is becoming increasingly important, new approaches for modeling and analyzing spatio-temporal data structures may be called for that make allowances for nonstationarity in time and/or space. Hierarchical spatial models that incorporate spatial correlation structures implicitly by considering parameters of a spatial model not as fixed quantities but as random variables at different temporal and/or spatial scales offer great promise in this regard.

**CONCLUSION**

Projected advances in computer processing and storage capacity suggest that in the near future, such massive amounts of data will be collected and stored that very little data will ever see the human eye; rather, data will be automatically processed and relevant information graphically displayed. Thus, spatial data will become increasingly available and the ability of plant and crop scientists to understand the spatio-temporal dimensions of agriculture will become increasingly important in the production and marketing of food. Both GIS and geostatistics will be tools of choice for plant and crop scientists as they strive to manage and understand the spatial nature of agricultural data.

Spatial Distribution of Weeds

J. A. “Anita” Dille
Kansas State University, Manhattan, Kansas, U.S.A.

INTRODUCTION

Individual weed species do not occur randomly or uniformly but as part of aggregated or patchy populations in agricultural fields. Furthermore, population densities vary greatly across individual fields such that there are areas of no weeds mixed with areas containing weeds that range from low- to high-density populations. If we can characterize the spatial distribution of weeds and understand the causes that generate this distribution, site-specific weed management systems can be developed.

CHARACTERIZING THE SPATIAL DISTRIBUTION OF WEEDS

The spatial distribution of weeds can be described by conducting surveys to collect specific location information across multiple sampling points. Two main types of weed survey methods include grid-based and remote-sensing approaches.

In a grid-based approach, weed species are identified and counted with a quadrat-sampling frame, typically 1 m², located at specific grid-intersection points in a given area (Fig. 1). These intersection points can be regularly or randomly distributed throughout the area. The grid spacing used in various research studies has varied from 7- to 24-m intervals.[1–3] The appropriate scale to assess the spatial distribution of weed populations, and subsequent choice of sample grid spacing, will depend on the desired end use of the spatial information. For regional management of noxious weeds, general geographic regions where the species occurs can be identified.[6] At the individual field level, a grower may indicate that a certain weed species is a problem in the entire northwest corner of the field, but once surveyed, individual patches can be identified within that corner.[1,2] (Fig. 2). For weed population dynamics modeling, small grid spacing is appropriate to obtain detailed weed information.[5] From a site-specific weed management perspective, information on the equipment to be used for weed control, such as the width of the spray boom or tillage equipment, will likely mandate larger grid spacing.[6]

Data from individual field surveys typically have frequency distributions with 60–90% of the sample sites having no weed seedlings, whereas a small number of sample sites have densities ranging from 60–200 seedlings/m².[3] Spatial statistics (geostatistics) can be used to further describe and map spatial distributions of weeds where standard statistical approaches are confounded by spatial autocorrelation; that is, data collected from sites closer in space are more closely related than data from sites further away in space.[3,7–10]

In a remote-sensing approach, aerial images of color or spectral reflectance are obtained from ground-, airplane- or satellite-based equipment and provide pixilated data (contiguous 1-m² pixels, for example) of agricultural fields. Weed populations must then be discriminated from crop, soil, and other residues in the image based on unique spectral signatures[11,12] or image analysis.[13] Remote-sensing approaches automate the procedure of surveying fields. Two challenges include obtaining aerial images in a timely fashion, such as when in-season weed control decisions must be made, and ensuring that weed populations are being captured in the image by on-the-ground sampling.

Data obtained from these two approaches are used to generate maps of the spatial distribution of weeds, providing population estimates at unsampled locations across the field if using the grid-based approach[5] or estimates of weedy ground cover using the remote-sensing approach.[12] Maps of the spatial distribution of weeds are used to develop maps that direct application of weed control practices. A weed control practice, such as herbicide or tillage applications, is applied if the weed population density at a given location is above a treatment threshold.[14–16] This is the basis of a site-specific weed management system.

CAUSES FOR SPATIAL DISTRIBUTION OF WEEDS

In an agricultural row crop environment, abiotic, biotic, and human factors contribute to the spatial distribution pattern of weeds. Understanding the extent to which each factor contributes to the pattern could lead to improvements in site-specific weed management. Abiotic factors include topography, soil texture, soil pH, organic carbon, and soil fertility, which vary spatially in fields. Spatial
Correlation exists between certain abiotic factors and weeds, and causes have been hypothesized. For example, certain weed species may emerge through a soil-applied herbicide that has interacted with soil texture and organic matter making it less active for weed control. Another is that variation in soil fertility or available soil moisture will influence crop and weed growth, competitive interactions, and potential weed seed productivity.

Biological characteristics of weeds and additional biotic factors in the environment can influence their spatial distribution. Often, weed seedlings are clustered around the parent plant because of localized seed dispersal, enhancing patchiness. Alternatively, the extent of clustering depends on activity of dispersal agents (wind, animals), weight and shape of weed seed, distribution of parental plants in the field, and potential longevity of seed in soil. Seedling emergence patterns are influenced by spatially variable soil temperature and moisture in the field and by higher survival of seedlings in response to soil- and foliar-applied herbicides in high-rather than low-density populations. Individual shoots of perennial weeds, such as Canada thistle, hemp dogbane, and johnsongrass, show spatial aggregation caused by clonal growth.

Human factors include all agricultural practices employed such as soil tillage, crop choice, weed control methods, and harvesting procedures. Patchiness may be reduced because of soil tillage practices or harvesting equipment spreading weed seed or perennial shoots away from the location of the parent plant. Patchiness is enhanced through weed control application errors such as sprayer skips or poor crop establishment resulting in less competitive crop environment against weeds.

Seed and seedlings of most weed species generate a patchy spatial distribution. However, numerous studies and observations have indicated that these patterns are highly irregular. The spatial distribution of weed species is a result of complex interactions of abiotic, biotic, and human factors.

**FUTURE PROSPECTS**

The fact that individual weed species are neither randomly nor uniformly distributed has implications in 1) developing efficient scouting protocols to accurately estimate weed population densities, 2) predicting yield losses caused by those densities, and 3) managing weed populations using site-specific weed management systems. Research continues in the areas of scouting for weed populations so that it will be less labor intensive while still providing detail. For example, real-time reflectance or image analysis sensors are being developed that can detect weeds and activate herbicide “patch” sprayers as equipment is driven through the field.

Understanding the spatial distribution of weeds, where they occur and why, has the potential to more accurately apply weed control practices where and when needed, change crop and soil management practices to discourage weeds, and reduce economic and environmental costs associated with weed control.

INTRODUCTION

The seeds of cereals are an important metabolic sink and an essential source of human and animal nutrition. Information on the biosynthetic pathways of carbohydrates, amino acids, and vitamins in crops provide the basis for the metabolic engineering of plants with improved nutritional profiles. In plants, pathways leading to starch, amino acids, and vitamins have been investigated in some detail at the level of enzymes and their cognate genes, but quantitative aspects of carbon flux including transport processes under in vivo conditions have been investigated less comprehensively.

Although it is clear that isotope incorporation studies can contribute important metabolite flux information, most isotope incorporation studies in the literature are limited to simple concepts that assume metabolism proceeds in a linear and unidirectional fashion. Based on this implicit assumption, the diversion of isotope from a given precursor to a given target compound is accepted as evidence for direct metabolic relatedness between the respective molecular species. In reality, however, metabolism is a complex and nonlinear network, and metabolic flux can occur from any node in the network to virtually any other node. As a consequence, isotope incorporation studies have been repeatedly plagued by remarkable errors of interpretation.

Recently, relatively fail-safe alternatives using general 13C-labeled precursors (such as glucose or acetate) have been developed for the quantitative assessment of carbon fluxes in microorganisms and plants. As an example, this article describes studies on the formation of starch in kernel cultures of maize.

ISOTOPOMER EQUILIBRIA

Terrestrial carbon is an isotopic mixture of 98.9% 12C, 1.1% 13C, and traces of 14C. Consequently, all organic compounds are complex isotopomer mixtures. For any 6-carbon compound (e.g., glucose), the number of nonradioactive carbon isotopomers is $2^6 = 64$. The isotopomer composition of glucose with natural 13C abundance is close to the state of chemical equilibrium; minor deviations caused by isotope selectivity of enzymatic reactions are below the level of sensitivity of the method used in disturbance studies and thus can be disregarded. The approximate abundances of different isotopomers in naturally occurring glucose are summarized in Fig. 1(A). Isotopomers that are labeled with 13C at multiple positions do not occur in significant amounts. Notably, the sum of the concentrations of all naturally occurring isotopomers with two or more 13C atoms in glucose with natural isotope abundance is less than 0.07 mol%.

The quasi-equilibrium isotopomer distribution of biomatter can be perturbed by the introduction of any singly or multiply 13C-labeled metabolite. Cellular metabolism is then conducive to a complex relaxation process in which virtually all chemical reactions occurring in the experimental system are involved. Whereas catabolic processes direct the system to a new equilibrium state (characterized by an increased 13C abundance in the case of closed systems), anabolic processes are conducive to metastable states that can be gleaned from the assimilated biomass (i.e., proteins, polymeric carbohydrates, lipids). It is obvious that enzyme reactions involving the breaking or formation of carbon/carbon bonds play a central role in these relaxation processes.

A detailed analysis of the isotopomer populations formed by the enzyme-catalyzed relaxation processes in the wake of a perturbation (by introduction of a multiply-labeled metabolite) is possible by nuclear magnetic resonance (1) (NMR) analysis[1] and affords an abundance of information that can not be obtained by traditional experimental setups that monitor global isotope enrichment or enrichment at selected positions but fail to document the quantitative composition of the entire isotopomer population.

ANALYSIS OF STARCH BIOSYNTHESIS IN KERNELS OF MAIZE

Using this methodology, the biosynthesis of starch was studied with immature maize kernels that were grown in sterile cultures and then supplied with a mixture of
After growth, starch was hydrolyzed and the resulting glucose was isolated and analyzed by quantitative NMR spectroscopy. The detailed description of the NMR analysis has been published, and will not be repeated here.

Of the 57 $^{13}$C-isotopomers of glucose that were labeled at more than one position, six occurred with an abundance above 0.08 mol% (Fig. 1(B)), i.e., well above their stochastic occurrence in natural abundance glucose (Fig. 1(A)). Notably, the abundance of [U-$^{13}$C$_6$]glucose in the sample is nine orders of magnitude above the level of that isotopomer in natural abundance glucose. Two isotopomers carrying single $^{13}$C atoms ([3-$^{13}$C$_1$]- and [4-$^{13}$C$_1$]glucose) also occurred with increased abundances of 1.46 and 1.31%, respectively, due to the metabolic processes.

The relative paucity of the [U-$^{13}$C$_6$]-isotopomer (0.19 mol%) shows that the carbon skeleton of the vast majority of the proffered carbohydrate precursors had been broken and reassigned at least once. Glycolysis followed by gluconogenesis results in breaking of the C3/C4 bond of glucose. Passage of glucose through the pentose phosphate pathway during regeneration of a hexose is conducive to breaking the C2/C3 bond (transketolase activity, Fig. 2) and/or the C3/C4 bond (transaldolase activity) of hexoses. Evidence for both processes is immediately obvious from the relatively high abundance of [1,2-$^{13}$C$_2$]-, [1,2,3-$^{13}$C$_3$]-, [4,5,6-$^{13}$C$_3$]-, [3,4,5,6-$^{13}$C$_4$]-, and [2,3-$^{13}$C$_2$]-isotopomers (Fig. 1).

The [5,6-$^{13}$C$_2$]- and [4-$^{13}$C$_1$]-isotopomers can be explained by the cooperative action of the pentose phosphate pathway and the glycolysis/gluconogenesis pathways (Fig. 3). Thus, the transfer of a [15C$_2$]-fragment from [U-$^{13}$C$_6$]fructose 6-phosphate to unlabeled erythrose 4-phosphate derived from unlabeled glucose generates [1,2-$^{13}$C$_2$]pentulose 5-phosphate and, subsequently, [1,2-$^{13}$C$_2$]hexoses (via transketolase catalysis) (Fig. 2). Glycolysis can produce [2,3-$^{13}$C$_2$]dihydroxyacetone phosphate from the double-labeled hexose, which yields [2,3-$^{13}$C$_2$]glyceraldehyde 3-phosphate by the catalytic action of triose phosphate isomerase. Regeneration of a hexose from [2,3-$^{13}$C$_2$]glyceraldehyde phosphate, either by gluconogenesis or via the pentose phosphate pathway could afford the [5,6-$^{13}$C$_2$]glucose isotope observed in our experiment (0.27 mol%) (Fig. 3). The abundance of the [5,6-$^{13}$C$_2$]-isotopomer is only slightly lower (about 30%) than that of the [1,2-$^{13}$C$_2$]-isotopomer from which it is proposed to be formed by the sequence of events described earlier. This suggests that the interconnection of the pentose phosphate pathway and the glycolysis/gluconogenesis pathways is operating quite efficaciously. More specifically, the data indicate that 87% of the glucose moieties of this

---

**Fig. 1** Molar abundance of $^{13}$C isotopomers of glucose. A. In natural abundance material; B. In starch hydrolysate from maize kernels supplied with [U-$^{13}$C$_6$]glucose and unlabeled glucose at a ratio of 1:40 (w/w).
precursor are not directly derived from external glucose; the hexose is recycled with high efficiency by the pentose phosphate pathway and glycolysis/glycogenesis, prior to their fixation in starch via the well known intermediate ADP-glucose\(^{[3]}\) (Fig. 4).

Plant metabolism is a very complex network, even when only carbohydrate metabolism in a maize endo-sperm cell is under investigation. Metabolic reactions involving hexoses take place in the cytosol and in the amyloplast of these cells. In fact, with the exception of the nonoxidative branch of the pentose phosphate pathway—which is localized in the maize plastid\(^{[4]}\)—both compartments harbor redundant sets of enzymes catalyzing both anabolic and catabolic reactions. The metabolite pools of the cytosol and the amyloplast are efficiently connected by transporters for triose phosphate,
hexose phosphate, pentose phosphates, and ADP-glucose that enable metabolite flux and maintain the phosphorus balance in the different compartments of the cell\[5\] (Fig. 4). In this context, the extensive cycling processes inferred from the glucose labeling pattern describes a flexible metabolic network that serves the physiological needs of the cell.

**CONCLUSION**

The perturbation of $^{13}$C-isotopomer equilibria by general $^{13}$C-labeled precursors (e.g., glucose) can serve to analyze carbon fluxes in complex metabolic networks with high resolving power. Many biosynthetic isotopomers of glucose can be assessed quantitatively by NMR analysis and provide detailed information about carbon-carbon connectivities that had been either retained or broken and regenerated during the metabolic conversion of glucose into starch. The technique can now be exploited to investigate and compare glucose flux under different physiological conditions.

**Striga: A Subterranean Parasitic Angiosperm (Witchweed)**

John I. Yoder  
*Department of Plant Sciences, University of California-Davis, Davis, California, U.S.A.*

Lytton John Musselman  
*Department of Biological Sciences, Old Dominion University, Norfolk, Virginia, U.S.A.*

**INTRODUCTION**

*Striga* is a parasitic angiosperm that invades the roots of other plants to rob them of water and essential nutrients. The effects on the host plant can be debilitating, and *Striga* is among the world’s most destructive agricultural pests. The success of *Striga* as an agricultural weed is owing in large part to its intimate and obligatory association with its host plant. At several stages in its life cycle, *Striga* uses chemicals that are released by the host to trigger developmental events critical for the parasitic lifestyle. The host–parasite communication system provides genetic targets for the development of resistant crop varieties.

**STRIGA TAXONOMY**

*Striga* is the genus of root parasites in the plant family Orobanchaceae. All of the 30 or so genera of Orobanchaceae are root parasites that realize at least some nutritional value by parasitizing other plants.[1] The effects on the host plants can be debilitating, and some of the world’s most destructive agricultural weeds are parasitic Orobanchaceae, the most important of which is *Striga*.[2] Of primary agricultural concern are two species that parasitize cereal crops, *Striga hermonthica* and *S. asiatica*, and one that parasitizes broadleaf dicots, *S. gesnerioides* (Fig. 1).

*Striga* is found in Africa, Arabia, East Asia, India, China, Indonesia, and Australia. Despite quarantine restrictions against *Striga* in U.S.A., there have been sporadic infestations of the Carolinas in the 1950s, which was the target of an extensive control and eradication program.[3]

**AGRICULTURAL SIGNIFICANCE OF STRIGA**

*Striga* is colloquially known as witchweed, because it “bewitches” the growth of crops before it appears above the ground. Parasitism by *Striga* results in stunted growth and yellow- or brown-wilted leaves (Fig. 1C and E). The degree of host damage is in part dependent on the host–parasite ratio. However, the reduction in host biomass exceeds the corresponding increase in the parasite; so clearly *Striga* causes pathogenesis beyond nutrient deprivation.

Because *Striga*’s host range includes food crops of many poor farmers in lesser-developed countries, it has an enormous impact on food security. Approximately two-thirds of agricultural land in sub-Saharan Africa is infested with *Striga*, and complete losses to maize, sorghum, and millet crops may occur. *Striga* is a primary biotic constraint to agricultural production throughout much of the semiarid world.[4]

**STRIGA BIOLOGY**

As a parasitic plant, *Striga* straddles the boundary between autotrophy and heterotrophy with about half its life taking place underground (Fig. 2). Without sunlight, achlorophyllous seedlings gain nutritional needs by invading the roots of nearby host plants through invasive structures called haustoria. *Striga* lives about six weeks as an obligate, subterranean parasite before emerging from the soil to flower. While *Striga* species perform limited photosynthesis after emergence, the bulk of fixed carbon in the parasite is obtained from the host.[6]

Key to *Striga*’s success is a remarkable host plant recognition system based on the perception of info-chemicals released by host roots. *Striga* and other Orobanchaceae use host molecules to induce developmental events associated with plant parasitism.[7] The developmental stages in *Striga* that depend on host factors are targets for developing genetic resistances in crops.

**Germination**

A single *Striga* plant produces hundreds of thousands of tiny seeds (0.3–0.5 mm) that are dispersed by wind and water in nature but spread more widely through contaminated seed. Because *Striga* must attach to a host root within a few days of germination, seed germination is carefully regulated to ensure parasitism. *Striga* seeds
must first be imbibed with water at particular temperatures and then exposed to factors exuded from host roots that stimulate *Striga* germination.

The potential to use germination factors to precociously germinate *Striga* in the absence of host crops motivated early biochemical efforts to identify the active molecules. Parts of Fig. 2, i.e., 2 and 3, diagram strigol, the first of several natural and synthetic germination factors identified. Most are sesquiterpene lactones that are active at picomolar concentrations. Unfortunately the biosynthesis of these molecules is complex and their use as control agents in subsistence farms field settings has not been possible.

**Haustorium Development**

A germinated *Striga* seed will produce a radicle superficially resembling other plants. However, the radicle will not develop beyond about 5 mm, unless a host root is contacted. Upon contact with the host, the *Striga* tip differentiates into a primary haustorium, a bulb-shaped structure covered by long epidermally derived hairs. These haustorial hairs exude factors that bind the haustorium to the host root. An infection peg...
then penetrates the host through a combination of enzymatic and intrusive growth.

Early haustorium development can be induced in vitro by applying host root exudates or purified root factors to the parasite root. This has allowed the identification of certain phenolics and quinones, collectively termed “xenognosins,” with haustorium-inducing activity.\(^9\)

**Postinvasion Events**

Once the haustorium penetrates the host, another set of host infochemicals influence *Striga* maturation. An obvious manifestation of host-affected haustorium maturation is the development of xylem elements that connect host and parasite vasculature. These can be observed within two days of host–parasite contact. Typical phloem elements are not observed, and the transport of water, sugars, and inorganic minerals is through transfer cells and xylem.

The *Striga* stem continues to grow toward the surface and extends secondary roots into the soil. Secondary roots can develop haustoria on their lateral surfaces, which further invade host roots. A mature *Striga* plant can have an extensively branched root system with numerous haustoria invading a single or multiple host roots. The *Striga* life span from germination to seed set is about three months, the entire period of which it continues to feed off the host.

**CONCLUSIONS**

*Striga* is the representative of a small group of organisms at the juncture between autotrophy and heterotrophy. *Striga* is also a devastating parasitic weed that affects some of the poorest farmers on earth, and novel control strategies are needed. Multiple stages in *Striga*’s life cycle require chemical signals that are made by the host plant, and these developmental stages provide genetic targets for weed-control interdiction.

Sucrose

Ed Etxeberria
University of Florida, Lake Alfred, Florida, U.S.A.

INTRODUCTION

Sucrose plays a unique role in the plant kingdom. Aside from being the primary product of photosynthesis and the main form of carbon transport in plants, sucrose constitutes the most abundant form of soluble storage carbohydrate and also serves as a signaling molecule that triggers essential metabolic events. Furthermore, sucrose plays a key role in plant reproduction and propagation. In nectars, sucrose concentration can determine the type and frequency of visiting pollinators, which may change with the sexual state of the flower, and its presence in fruits serves as an attractant to animals for seed dispersal. A readily available source of energy, sucrose sustains the initial stages of growth after dormant periods in temperate plants. From photosynthetic cells in leaves to heterotrophic root cells, sucrose is found in virtually every living plant cell. There are other soluble saccharides present in plants, and in all cases they are accompanied by high levels of sucrose. In effect, sucrose is the ultimate building block for all other organic compounds in plants and most other carbohydrates in nature, given the position of plants as the cornerstone of the energy food chain.

WHY SUCROSE?

The reason for the ubiquitous position of sucrose in the plant kingdom is not evident. In comparison with trehalose, the other prominent disaccharide found in nature with equivalent functions in insects and fungi, and with raffinose-based saccharides, which are commonly found in various plant species, several conjectures have been made. Based on the process of natural selection to perform equivalent functions, the general premise is that these molecules must share important properties that impart physiological advantages. A common characteristic to all aforementioned saccharides is their nonreducing nature. Nonreducing molecules are less reactive and less susceptible to breakdown by the cellular enzymatic milieu. Their high energy of hydrolysis conserved in their glycosidic linkage makes these molecules more valuable as energy currency and as a readily available carbon source. Two other disaccharides found in living systems, maltose and lactose, have glycosidic linkages with less than half the energy of hydrolysis of sucrose. Finally, both of these molecules have been shown to protect membrane lipids during dehydration and freezing, and to help stabilize organelles and proteins.

FROM PHOTOSYNTHETIC PRODUCT TO THE PHLOEM STREAM

In green cells, glucose 1-phosphate and fructose 6-phosphate are synthesized in the cytosol from triose-phosphates that are produced in the Calvin cycle and exported from the chloroplast. Sucrose is synthesized from UDP-glucose and fructose-6-phosphate in a sequence of two reactions catalyzed by sucrose-phosphate synthase (SPS) and sucrose-phosphate phosphatase (SPP). Both enzymes are localized in the cytosol and appear to form a metabolic unit during synthesis. Regulation of sucrose synthesis is a complex system that involves fine and coarse control. Although some controlling elements have been described, it is likely that other factors yet to be discovered may contribute to the overall regulation and may modify prevailing opinions about sucrose synthesis. In photosynthetic cells, newly synthesized sucrose has two potential fates depending on cellular, physiological, and environmental factors. Sucrose is either stored in the vacuole and/or exported to supply carbon to heterotrophic cells. Temporary storage of excess sucrose in the vacuole usually takes place at times of high photosynthetic activity and limited phloem loading capacity. The mechanisms of sucrose transport into the vacuole of green cells are not fully understood, but the process is believed to be mediated through a passive transport mechanism.

The movement of sucrose from mesophyll cells to the phloem elements can take various routes depending on the plant species, and it involves different cell types (Fig. 1). One route consists of intracellular symplastic movement of sucrose across the plasmodesmata of leaf cells and eventual release into the sieve element/companion cell...
In the second route, sucrose is released into the extracellular apoplast at some point, where it diffuses through the cell wall milieu. After reaching the SE/CC complex, sucrose is retrieved by the well-characterized plasmalemma-bound sucrose/H⁺ symport. Accumulation of sucrose in the SE/CC increases the hydrostatic pressure, which drives mass flow transport to other plant parts via the phloem.

(Fig. 1) The cycle of sucrose in a plant, from its synthesis to its storage and utilization. Synthesized in the leaves from photosynthetic products, sucrose is exported to support heterotrophic cells and/or stored temporarily. Along the transport route, the involvement of several carriers is required, either for retrieval of leaked sucrose or as part of the apoplastic route. Once stored, the direction of sucrose transport is reversed to sustain developing plant parts. Loss of sucrose to herbivore consumption can occur at many points along the route. (View this art in color at www.dekker.com.)

From the Phloem to Heterotrophic Cells

It is not known whether release of sucrose along the phloem pathway or at the sink end of the phloem route is also proton coupled, occurs by diffusion, or involves transport through the symplast along heterotrophic cells. Sieve element unloading invariably includes an apoplastic component, but its contribution to the overall unloading process depends on many factors and seems to be restricted to specialized circumstances and tissues.

Symplastic unloading and transport apparently constitute the principal unloading route. In most cases, there is evidence indicating that sucrose exits the phloem cells and is transported to heterotrophic cells through plasmodesmata connections. Although plasmodesmata connections are present along the entire length of the transport path, efflux seems to occur only at specific regions (Fig. 1).

That sucrose and other photoassimilates are transported into heterotrophic cells through the symplast has been largely inferred from the existence of plasmodesmata connections, the observed transport of large protein or fluorescent probes to the storage cells, and the use of transport inhibitors and transgenic plants. However, the presence of plasmodesmata is not a universal characteristic within heterotrophic cells, and transport through the apoplast is undoubtedly required in some instances. The apoplastic route is necessary in cases where there is symplastic discontinuity between two tissues, as is the case for filial and maternal tissue in developing seeds. Once released into the apoplast, sucrose may be hydrolyzed into glucose and fructose.
by cell wall–bound invertases to maintain a concentration gradient. The situation is quite complicated, given that in some organs (such as potato) both types of postphloem transport take place, depending on developmental stage.

## STORAGE OF EXCESS SUCROSE

Whereas some of the sucrose entering the cell is utilized to satisfy immediate metabolic demands, excess sucrose is stored in the vacuole for future needs. The mechanism of sucrose transport into the vacuole of heterotrophic cells depends on its entrance pathway into the cell. Symplastically loaded sucrose needs to traverse only one membrane barrier into the vacuole: the tonoplast, which is believed to possess a sucrose/H⁺ antiport. Such an antiport system has been identified at the tonoplast of a few storage cells such as red beet (*Beta vulgaris*) and Japanese artichoke (*Stachys sieboldii*), but this system is conspicuously absent from the high-sucrose-storing cells of sugarcane (*Saccharum officinarum*) and sweet lime (*Citrus limettioides*).

Where sucrose unloading takes the apoplastic route, the plasmalemma offers an additional barrier to accumulation. A sucrose symporter similar to that located at the plasmalemma of SE/CC is presumed to carry sucrose into the cytosol. However, a plasmalemma-bound sucrose symport in storage cells has been inferred from gene expression studies, but its activity has never been demonstrated directly. More recently, an endocytotic system of transport has been proposed to carry sucrose (and other dissolved solutes) from the apoplast to the vacuole of storage cells. Endocytotic vesicles would transport solutes to be stored directly into the vacuole, whereas the plasmalemma-bound sucrose symporter allows the passage of sucrose required by cytosolic activities. In this way, the cytosolic homeostasis is not disrupted by the constant fluctuations of the phloem contents (Fig. 1).

## UTILIZATION AND MOBILIZATION OF RESERVE SUCROSE

Metabolic demands for long-term stored vacuolar sucrose occur in vital processes such as resumption of growth in dormant or reproductive tissues, seed germination, and the maintenance of cell viability in stored commodities. Depending on metabolic demand, stored sucrose can be mobilized by storage cells to supply their own physiological requirements and those of remote cells, such as developing shoots, roots, and reproductive organs. Therefore, the mechanisms of sucrose export depend on the ultimate fate of the disaccharide. For internal metabolic use, sucrose can be exported from the vacuole to the cytosol by an ATP-dependent sucrose pump.[7] The exported sucrose can be either released as a disaccharide or catabolized after export by sucrose synthase, which forms a metabolic unit with the ATP-dependent sucrose pump to release UDP-glucose and fructose.

For external transport, a reverse vesicle-mediated system (exocytosis) carries sucrose and other vacuolar substances to the apoplast[8] (Fig. 1). Once released into the apoplast, sucrose is transported to growing points throughout the plant to maintain growth, and in a large number of biennial plants, to sustain the entire second year reproductive activities. In many ways, sucrose secretion as part of flower nectar follows a similar exocytotic route. However, it is believed that some solutes in the nectar originate in other cellular organelles and that a more complex network of vesicle transport is involved.[8]

## COMPLETING THE CYCLE

Whether originating from the storage organs or from neighboring exporting photosynthetic leaves, sucrose provides the energy for the development of new leaves until they become fully autotrophic. A series of soluble and wall-bound invertases, in addition to sucrose synthase, channel sucrose to different metabolic pathways. Once the leaf becomes an autotrophic organ, the direction of sucrose flow reverses and export of sucrose renews the cycle. Therefore, as the primary product of photosynthesis, sucrose powers life on earth by virtue of being the basic fuel for life.

Sustainable Agriculture and Food Security

Jules Pretty
University of Essex, Colchester, U.K.

INTRODUCTION

Despite several decades of remarkable agricultural progress, the world still faces a massive food security challenge, with an estimated 790 million people lacking adequate access to food. Most agree that food production will have to increase in the coming years, and that this will have to come from existing farmland. But solving the persistent hunger problem is not simply a matter of developing new agricultural technologies. Most hungry consumers are poor, and so simply do not have the money to buy the food they need. Equally, poor producers cannot afford expensive technologies. They will have to find solutions largely based on locally available natural, social and human resources. The key questions are, therefore, to what extent can agricultural systems become more productive while not causing harm to the environment, and do such systems offer any new hope for the hungry?

SUSTAINABLE AGRICULTURE

Something is wrong with our agricultural and food systems. Despite great progress in increasing productivity in the last century, hundreds of millions of people remain hungry and malnourished. More hundreds of millions eat too much, or the wrong sorts of food, and it is making them ill. The health of the environment suffers too, as costly degradation seems to accompany many of the agricultural systems we have evolved in recent years. Can nothing be done, or is it time for the expansion of another sort of agriculture, founded more on ecological principles and in harmony with people, their societies and cultures?

In the earliest surviving texts on European farming, agriculture was interpreted as two connected things, agrí and cultura, and food was seen as a vital part of the cultures and communities that produced it. Today, however, our experience with industrial farming dominates, with food now seen simply as a commodity and farming often organized along factory lines. To what extent can we put the culture back into agri-culture without compromising the need to produce enough food? And can we create sustainable systems of farming that are efficient and fair, and founded on a detailed understanding of the benefits of agroecology and people’s capacity to cooperate?

As we advance into the early years of the 21st century, we have some critical choices. Humans have been farming for some 600 generations, and for most of that time the production and consumption of food has been intimately connected to cultural and social systems. Foods have a special significance and meaning, as do the fields, grasslands, forests, rivers, and seas. Yet in just the last two or three generations, we have developed hugely successful agricultural systems based on industrial principles. In most cases they produce more food per hectare and per worker than ever before, but they look so efficient only if we ignore the harmful side effects—the loss of soils, the damage to biodiversity, the pollution of water, and the harm to human health.

Over these 12,000 years of agriculture, there have been long periods of stability, punctuated by short bursts of rapid change. These changes resulted in fundamental shifts in the way people thought and acted. We are at another such junction. A sustainable agriculture making the best of nature and of people’s knowledge and collective capacities has been showing increasingly good promise. But it has been a quiet revolution, because many accord it little credence. It is also silent because those in the vanguard are often the poorest and the marginalized, whose voices are rarely heard in the grand scheme of things. No one can exactly say where this revolution could lead us. Neither do we know whether models of sustainable production would be appropriate for all farmers worldwide, but the principles do apply widely. Once these come to be accepted, then it will be the ingenuity of local people that shapes these new methods of producing food to their own particular circumstances.

We know that most transitions involve trade-offs. A gain in one area is accompanied by a loss elsewhere. A road built to increase access to markets helps remote communities, but it also allows illegal loggers to remove valuable trees more easily. A farm that eschews the use of pesticides benefits biodiversity, but may produce less food. New agroecological methods may mean more labor...
is required, putting an additional burden on women. But these trade-offs need not always be serious. If we listen carefully and observe the improvements already being made by communities across the world, we find that it is possible to produce more food while protecting and improving nature. It is possible to have diversity in both human and natural systems without undermining economic efficiency.

**RECENT DEVELOPMENTS**

In recent research, we examined the extent to which farmers have improved food production in recent years with low-cost, locally available, and environmentally sensitive practices and technologies. During 1999–2000 we analyzed by survey 208 projects in 52 developing countries, in which 8.98 million farmers have adopted these practices and technologies on 28.92 million hectares, representing 3% of the 960 million hectares of arable and permanent crops in Africa, Asia, and Latin America.

We found improvements in food production occurring through one or more of four mechanisms: 1) intensification of a single component of a farm system; 2) addition of a new productive element to a farm system; 3) better use of water and land, thereby increasing cropping intensity; 4) improvements in per-hectare yields of staples through introduction into farm system of new regenerative elements, locally appropriate crop varieties, and animal breeds. The 89 projects with reliable yield data show an average per-project increase in per-hectare food production of 93% (Fig. 1).

There are several key practices and technologies that have led to these increases: increased water use efficiency, improvements to soil health and fertility, pest control using biodiversity services with minimal or zero-pesticide use, and social organization for collective action.

This research reveals promising advances in the adoption of practices and technologies that are likely to be more sustainable, with substantial benefits for the rural poor. With explicit support through national policy reforms, better markets, and more integrated and cross-disciplinary approaches to science, these improvements in food security could spread to much larger numbers of farmers and rural people in the coming decades.

Social learning is a vital part of the process of adjustment in sustainable agriculture projects. The conventional model of understanding technology adoption as a simple matter of diffusion, as if by osmosis, no longer holds. But the alternative is neither simple nor mechanistic. It involves building the capacity of farmers and their communities to learn about the complex ecological and biophysical complexity in their fields and farms, and then to act in different ways. The process of...
learning, if it is socially embedded, provokes wider changes in behavior.

Farmers require timely information on pest–predator relationships, moisture and plants, soil health, and the chemical and physical relationships between plants and animals. These are subject to manipulation—and farmers who understand this, and who are confident about experimentation, are better innovators. The empirical evidence tells us two important things. Social learning leads to greater innovation, and there is increased likelihood that social processes producing these technologies are likely to persist.

**CONCLUSION**

Several things are now clear with respect to sustainable agriculture:.[3]

- The technologies and social processes for local-level agroecological improvements are well-tested and established.
- The social and institutional conditions for spread are less well-known, but have been established in several contexts (in particular social groups at the local level and novel partnerships between external agencies.
- The political conditions for the emergence of supportive policies are the least established, with only a very few examples of real progress.

Most of the sustainable agriculture improvements seen in the past decade have arisen despite existing national policies, which will need major reform. Policies framed to deliver increased food production will have to be changed if they also are to help deliver environmental and social benefits. Food policies framed to help deliver cheap and abundant food, regardless of quality, will have to change as well. And rural development policies and institutions focusing on “exogenous” solutions to the economic and social problems of rural communities are ill-suited to the needs of community-based and participatory development.[6,11]

Nevertheless, there has been increasing global recognition of the need for policies to support sustainable agriculture.[3,8] Although almost every country would now say it supports sustainable agriculture, the evidence points toward only patchy reforms. Only three countries—Cuba, Switzerland, and Bhutan—have given explicit national support for sustainable agriculture, putting it at the center of agricultural development policy and integrating policies accordingly. Cuba has a national policy for alternative agriculture, Switzerland has three tiers of support to encourage environmental services from agriculture and rural development, and Bhutan has a national environmental policy coordinated across all sectors.

Some countries, such as in India, Brazil and Sri Lanka, have seen subregional support at the state level for zerotillage, watershed and soil management, and participatory irrigation management. A much larger number of countries have reformed elements of agricultural policies through new regulations, incentives and/or environmental taxes, and administrative mechanisms, and these are having considerable—though partial—effect. These changes include catchment approaches for soil conservation and bans on selected pesticides, combined with a national program for farmer field schools and integrated pest management (IPM) in rice, support for soybean processing and marketing, and regional integration of agricultural and rural policies. But most countries have not yet explicitly put sustainable agriculture at the center of their policy frameworks.

INTRODUCTION

Agricultural technology has increased farm production to unprecedented levels. However, returns on investments are diminishing and environmental concerns are in conflict with current chemically intensive farm practices. Emerging technologies—such as precision farming and genetically modified crops—can potentially improve farm management through reduced chemical use and better distribution of those chemicals. However, using these farm management strategies to redirect or change the types of chemicals needed continues the reliance on external chemical inputs that are reducing farm profit. To change this trend, management strategies must be redirected to promote sustainable and holistic management that encourages interdependent and diverse properties. With this redirection, use of chemicals can be relegated to a backup role, giving way to a management strategy that enhances and promotes the inherent strengths and processes of the agroecosystem.

NEED FOR CHANGE

Agricultural production in the United States has increased dramatically during the past 75 years. Corn production has nearly quadrupled from 1920 to 1995, while the crop acreage has been reduced by one-third.\(^1,2\) Such impressive crop yields stem primarily from the development and application of agricultural chemicals (pesticides and fertilizers), new and improved agricultural machinery, educational and extension programs, and improved plant cultivars resistant to pests and designed for higher yield. But these yield gains are showing diminishing returns even with increased inputs (Fig. 1), and have come at the expense of impaired natural resources and diminished soil and water quality.\(^3\) The two farm management practices most devastating to soil and water ecologies are intensive chemical use (pesticides and fertilizers) and tillage practices.\(^4\) High chemical use destroys soil microorganisms that decompose residue and aid in nutrient recycling; kills beneficial insects; and can, with water runoff and leaching, poison water resources. Agriculture is the leading source of wetland water quality impairment.\(^5\) Pesticide use causes destruction of natural enemies and increased pest resistance, thereby resulting in secondary pests, pest resurgence, and a treadmill of pesticide dependency. This dependency on chemical inputs creates an unstable farming enterprise that continues to spiral toward higher and higher chemical inputs to make up for the depletion of inherent resources on the farm. In the United States, crop losses due to pathogens, animal pests, and weeds have increased from 34.9% in 1965 to 42.1% in 1988–1990,\(^6\) despite a 170% increase in pesticide use over roughly the same period (1964–1985).\(^7\) Heavy tillage is an energy-intensive management practice that increases pollution and energy costs and removes soil cover, exposing it to erosion by wind and water. Compounding the issue for farmers is the rising per unit cost of inputs and the recent drop in commodity value. Recent commodity prices have combined with inclement weather patterns to force many farmers out of business. New sustainable management strategies must be developed to reverse the escalating economic and environmental consequences of conventional management practices. As argued by Lewis et al.,\(^7\) these new strategies must go beyond the mere ongoing replacement of therapeutics with alternative newer, more sophisticated intervention materials. Rather, truly satisfactory solutions require a shift to a systems approach to understanding and renewing the inherent strengths and balances of agricultural ecosystems, with therapeutic interventions serving strictly as backups to the natural components. This article defines and discusses the goals of sustainable agriculture as compared to conventional agriculture, and generally outlines the shift in operating philosophy required to achieve the new goals.

SUSTAINABLE VERSUS CONVENTIONAL AGRICULTURE PRACTICES

Sustainable agriculture is a management strategy that seeks to meet current production and profitability needs while protecting the long-term ecological health and...
production capacity of a system through fostering and utilizing inherent and renewable strengths. Sustainable systems are noted for six key attributes: diversity, self-renewal, self-sufficiency, self-regulation, efficiency, and interdependence.[8] Diversity and interdependence develop self-regulating mechanisms such as multitrophic interactions, self-renewing properties through nutrient recycling, and self-sufficiency through reliance on inherent resources. A sustainable system is thereby driven not by chemical and energy-intensive inputs, but by the development of renewable resources and inherent strengths within the agroecosystem. For example, by nurturing soil microbial and earthworm activity and nitrogen-fixing and cover crops, nutrients are replenished within the system, reducing the need for applied fertilizers. This requires an understanding and management of the interactions among vertebrates, invertebrates, plants, water, and soils to build on the inherent renewable strengths and resources of the agroecosystem.

In contrast, current farming practices are generally highly input-dependent and have eroded the inherent strengths of the agroecosystem. Monocultural practices, single-tactic strategies, and reliance on chemical pesticides and fertilizers as well as heavy soil tillage have created a system of farming that requires constant therapeutic inputs. This input-driven farming system is extremely inefficient, costly, and unstable as pest resistance and resurgence require continued heavy pesticide use (Fig. 2, current farming system). Subsequently, inherent strengths of the agroecosystem—such as the self-regulation of pests with beneficial insects—are eroded. As it becomes more difficult to farm for profitability, farmers look to new tools such as better chemical pesticides, precision agriculture, and genetically engineered crops to maintain production. However, these new technologies are still just therapeutic inputs that are not sustainable. Therefore, while efficiency and stability improve initially, the intrinsic ability of agroecosystems to neutralize external interventions causes the new inputs to lose their effectiveness, and instability returns, as the treadmill of input dependency continues (Fig. 2, upper arrow). This is very evident in the reaction of pests to new pesticides. Their efficacy is very high initially, but continually diminishes as pest resistance increases. A redirection in technology development toward sustainable agriculture

![Fig. 2](Image)

Conventional versus sustainable paths of farming systems.
will increase farming stability by fostering the natural ecological mechanisms that regulate pests and nutrient recycling. This is accomplished by fostering the inherent strengths of the farming enterprise and reducing therapeutic inputs to a backup role (Fig. 2, lower arrow).

**DECIPHERING ISSUES OF PROFITABILITY, YIELD, AND SUSTAINABILITY**

As yield increases have begun to plateau, input costs have continued to rise. Consequently, the cost of farming has increased and the price index has begun to flatten (Fig. 1). One factor that is important in determining profitability but that has not been accounted for since the advent of chemical fertilizers and pesticides is the utilization of the built-in, on-farm inherent strengths already described. Farming profit \(P\) is a function of the commodity yield \(Y\) and the money spent to produce that commodity \(I\). Inputs can further be divided into a numerator—therapeutic inputs \(I_1\)—and a denominator—inputs developed by utilizing the inherent resources on the farm \(I_2\). \(I_1\) is in the numerator because, as therapeutic input costs increase, profit is reduced. \(I_2\) is placed in the denominator because, as the inherent strengths of the system are utilized, they reduce \(I_1\) and increase the profit margin. The farming profit can then be represented by Eq. 1:

\[
P = Y - \frac{I_1}{I_2}
\]

where \(P\) = profit ($); \(Y\) = yield ($); \(I_1\) = input costs for seed, chemical fertilizer, pesticides, equipment, land, and fuel ($); \(I_2\) = agroecosystem (on-farm) resources and inherent strengths that are normally ignored ($).

The benefits of inherent strengths and on-farm resources \(I_2\) have not been utilized in a holistic manner and are practically invisible to the equation as long as therapeutic inputs are the driving force behind agricultural production. The resulting system is inefficient and unsustainable, as inputs continue to eat away at the farming base (Fig. 2, current farming system). New technologies are being developed in an attempt to reduce this dependency and improve the profitability of farming, but are only met with an ever-growing dependence on therapeutic and costly inputs (Fig. 2, upper arrow). For example, precision agriculture has helped redistribute chemicals across a field, but has to date not addressed the underlying causes of field variability and has not addressed potentially less intrusive solutions that utilize the inherent strengths of the agroecosystem. The inherent strengths and resources, when properly utilized and fostered in a sustainable manner as defined previously, act to reduce input costs \(I_1\) as sustainable strategies are put in place. Therapeutic inputs such as chemical pesticides are then reduced to a backup role in the development of inherent strengths and multiple interactions within the agroecosystem as a whole, improving the profitability and sustainability of the agroecosystem (Fig. 2, lower arrow). Eq. 1 becomes

\[
P = Y - \frac{I_1}{I_2}
\]

where \(I_1\) (therapeutic) inputs are reduced to a backup role in developing and utilizing inherent strengths \(I_2\).

It may be difficult to move from a conventional farm management system to a sustainable managed agroecosystem due to cultural biases, economic trends, and technological or knowledge limitations. Economic hardship usually has a negative impact on implementing sustainable practices. Paradoxically, there is a tendency to add more inputs in hopes of increasing production. Unfortunately, profits are typically reduced through increased production costs without a subsequent increase in production. There is also a reluctance to attempt practices that do not yet have a proven track record. Farmers who are successfully managing sustainable agroecosystems are few, making it difficult to demonstrate to farmers real-world, long-term benefits. Finally, developing and maintaining a sustainable agroecosystem and making systematic improvements year to year to improve sustainability requires knowledge of the mechanisms of self-regulating systems and tools for monitoring the factors that affect these mechanisms.

Each of these issues must be addressed if there is to be widespread acceptance of such practices. Cultural biases can be reduced by supporting farmers who develop these practices of sustainable and precision management, so they can become mentors for other farmers in the community. As successful practices emanate out, more widespread adoption will become possible. Farmers will also need the support of local community leaders who also practice these ecologically-based principles. Research and educational programs at federal, state, and local levels must be directed toward developing and understanding agroecosystems so that management practices are well-understood and adopted. Technological tools to monitor and assess the health of agroecosystems can provide databases that provide knowledge of sustainable practices. With increased knowledge, farmers can make informed decisions to manage sustainable agroecosystems more confidently.

**CONCLUSION**

Current farm production practices are not environmentally friendly and require high levels of chemical and mechanical inputs to maintain and manage. Besides the environmental consequences, the financial burden is high,
as chemical inputs are the driving force behind maintaining an acceptable level of production. To reduce the environmental and financial burden of current farm production practices, a fundamental shift in farm management strategies is needed to create a more sustainable farming system that preserves the long-term productivity of existing farmland with less reliance on chemical inputs and more reliance on developing farm resources and inherent strengths. These agroecosystems must be managed in a holistic manner, fostering biodiversity and multiple interactions at several scales. By developing farming systems that are sustainable, with therapeutic inputs reduced to a backup role, farmers can increase profitability and be less susceptible to adverse outside influences.

INTRODUCTION

Food production suffers from overpopulation and environmental degradation at a time when food shortages are critical. The World Health Organization recently reported that more than 3 billion people are malnourished in the world.\(^1\) This is the largest number and proportion of malnourished people ever in history. In the United States and throughout the world, agriculture suffers from many serious environmental problems that reduce the sustainability of crop and livestock production. The environmental resources most notably affected are soil, water, nutrients, energy, and biodiversity—all vital resources for food production.

Degraded agricultural lands require more fertilizers and more irrigation in order to maintain production. This is costly in terms of energy and the economics of agricultural production. In addition, the abandonment of some agricultural technologies (such as crop rotations) has resulted in loss of biodiversity and increased insect pests, plant pathogens, and weeds. These changes in turn require the intensive use of pesticides and other types of pest controls.

In addition to the direct effects of poor environmental resource management on agricultural production are the indirect effects off-site, such as pesticides and nitrogen fertilizer leaching and washing into rivers and groundwater. All of these negative effects reduce the sustainability of agriculture and the natural environment.

SOIL

World and U.S. food supplies depend on the availability of productive soils. Currently, more than 99.7% of world and U.S. food supply comes from the land, whereas less than 0.3% comes from the oceans and other aquatic ecosystems.\(^2\) Therefore, the dimensions of soil and land destruction in the United States and the world are of increasing concern. At present, the rate of soil erosion on U.S. cropland averages about 13 times greater than soil reformation. In Africa, Asia, and South America, the rate of soil erosion is 30 to 40 times greater than soil reformation. Soil erosion and land degradation result in the loss and abandonment of about 10 million hectares (ha) of cropland each year worldwide.\(^3\)

The abandonment of productive cropland coupled with the removal of forests is having negative impacts on world forests. Approximately 60% of world forest removal is associated with agricultural spread into forests.\(^2\)

Soil erosion is intensifying, especially in developing countries where poor people depend on biomass energy for cooking and heat.\(^4\) Wood fuel in most developing countries is in short supply, forcing the rural poor to turn to burning crop residues for cooking and heating their homes. The removal of crop residues leaves the soil unprotected from wind and water erosion. Without crop residues, soil erosion rates often increase tenfold. In addition, the crop residues contain nitrogen, phosphorus, and potassium—all essential nutrients for crop production. These vital nutrients are an integral part of the crop residues.

Erosion adversely affects crop productivity by reducing the availability of water, soil nutrients, soil biota, soil organic matter, and soil depth. The reduction in the amount of water available to the crop is considered the most harmful effect of erosion. After water, shortages of soil nutrients are the most important factors in limiting crop production.\(^1\)

Severe soil erosion and associated rapid water runoff problems now seriously diminish the food economy as well as the health of the environment in the United States and world. In total in the United States, soil erosion effects both on the farm and off-site on the environment are estimated to cause more than $45 billion dollars in damages yearly.\(^3\)

WATER

All crops require and transpire massive amounts of water. For example, a corn crop that produces about 8000 kg/ha takes up and transpires about 5 million liters of water during the growing season of a little over three months.\(^5\) If the corn crop requires irrigation, close to twice this much water (about 10 million liters) must be applied because not all the water is picked up by the corn plants.

Irrigation is highly energy intensive and costly. Approximately three times as much energy is required for crop production if the crop must be irrigated,
compared with requirements for a rain-fed crop. Between $1000 and $1500 is required to irrigate a hectare of land. Approximately 1000 liters of water are required to produce 1 kg of grain. In the United States and world, about 70% of all water used is applied to crops for irrigation.\(^5\)

Producing meat requires more water than crop production. For example, the production of 1 kilogram of beef requires about 43,000 liters of water. (This is not the water that a cow drinks; rather, it is the water required to produce the grain and forage that the cow consumes.)

Water and fossil energy are the two critical resources now limiting world food production.

**PESTICIDES**

Each year approximately 3 million metric tons of pesticides (insecticide, herbicides, and fungicides) are applied worldwide; approximately 500,000 tons are applied in the United States.\(^6\) Despite the heavy application of pesticides worldwide, pest insects, weeds, and plant pathogens destroy more than 40% of all potential crop production. Losses of crops to pests in the United States are similar to world losses, or about 37% of potential production.\(^6\) It should be pointed out, however, that food losses in each nation are related to cosmetic standards established in each nation. For example, fruits and vegetables sold in markets in India and Guatemala would generally not be salable in markets in the United States.

One concern over the use of pesticides is that less than 0.1% of the pesticide applied actually reaches the target pest. Thus, more than 99.9% disperses widely to contaminate the environment, including water and soil resources.\(^7\)

Although each dollar invested in pesticide control returns about $4 in protected crops, this benefit overlooks the environmental and public health costs of pesticide application. In the United States, pesticide use causes approximately $9 billion in damages to the environment and public health each year.\(^6\)

Related to the public health problems in the United States are about 110,000 nonfatal human pesticide poisonings each year. In addition, between 10,000 and 12,000 cases of cancer are annually associated with the use of pesticides. Worldwide, about 26 million nonfatal pesticide poisonings occur, resulting in approximately 220,000 deaths each year. During the past 15 years, Sweden has been able to reduce pesticide use by 68%, while at the same time reducing public health problems associated with pesticides by 77%. Several nations (including Norway, Denmark, the Netherlands, and Indonesia) and the Canadian province of Ontario have programs to reduce pesticide use by 50% or more.\(^6\)

**FOSSIL ENERGY**

The spectacular increases in grain and other crop yields during the past 40 years have been due to fossil energy inputs for fertilizers, irrigation, and pesticides. Thus, the green revolution was in reality due to the use of fossil energy. Grain crops such as rice and wheat were bred to be of short stature so they could produce increased yield in response to higher inputs of nitrogen fertilizer. The old

varieties of these crops with large inputs of nitrogen would grow tall and then fall over and rot. Therefore, short varieties were essential to allow large amounts of fertilizers to be applied.

SOUND ENVIRONMENTAL AND ECONOMIC AGRICULTURAL MANAGEMENT

The major difficulties associated with conventional high-input agriculture are 1) high costs of production; 2) serious environmental resource degradation; and 3) instability of crop yields. Numerous agricultural technologies can be implemented to make agriculture environmentally and economically sustainable. These technologies can reduce chemical inputs (including fertilizers and pesticides), reduce soil erosion and rapid water runoff, and make better use of livestock manure.

The economical and environmentally sound agricultural practice of ridge planting and the rotation system are compared with the conventional corn production system in Table 1. Note the high level of inputs in the conventional corn system. The total costs of these inputs average $844 per ha in the United States. The total energy input is 7.0 million kcal/ha. The yields in both systems are the same, 8000 kg/ha.[8]

In the ridge-planting system, employing a cover crop and crop rotation reduced soil erosion from about 20 t/ha/yr to about 1 t/ha/yr. No insecticides or herbicides were employed in this system, demonstrating that corn can be produced without these chemicals.

Environmentally and economically sound corn production required only 4.0 million kcal and cost only about $700 per ha (Table 1). These values were 44% lower for energy and 17% lower for economic inputs than conventional corn production.[9]

Sustainable Agriculture: Ecological Indicators

Stephen S. Jones
Washington State University, Pullman, Washington, U.S.A.

INTRODUCTION

Agricultural sustainability is a process rather than an end point. From a purely ecological view, the process leads to a system of food and fiber production that is in such a state of environmental health that it can continue at the given rate of extraction into the measurable future. To evaluate the progress or the status of sustainable systems requires measurable units. Following the precedence of economic models, the term used to describe such units is indicators. To monitor the biological robustness of a system then requires that these units be indicators that reflect on the entire ecology of the system, hence the term ecological indicators.

Ecological indicators go beyond the canary-in-the-coal mine analogy, in that the best indicators do not merely take an immediate assessment of the health of the system but should be able to be monitored over time. They should also be easily measurable, applicable to a wide range of systems, responsive to change, inexpensive, relevant, and easy to interpret. These indicators should also measure ecological health rather than the productivity of a system. Farm productivity, in many cases, may result in the reduced long-term health of a system.

Some very powerful indicators can also be very simple. For example, it is impossible for a system that loses soil more rapidly than it is replaced to be sustainable. As an indicator, then, soil erosion is a very obvious and relevant measurable unit. Other indicators may be far more subtle, however. Shifts in microorganism populations, soil tilth, and above- or below-ground flora and fauna may all have value in assessing the level of sustainability for a particular system. However, each is quite complicated to measure and monitor over time, and no single indicator can monitor an entire system. Thus, the use of indicators based on more holistic approaches is also being considered.

TYPES OF ECOLOGICAL INDICATORS

Indicators can be either biotic or abiotic. Abiotic indicators deal primarily with the general health of the soil relative to sustaining life, while biotic indicators involve the monitoring of various life forms. Holistic approaches to identifying biological indicators can involve such issues as farmer choice of cultural practices and indicators that can be used on a landscape level, as opposed to a single-field level. Holistic approaches are an attempt to move away from reductionist measurements of ecological systems.

Abiotic Indicators

Some abiotic indicators are obvious and require no measurement whatsoever. One such indicator is illustrated in Fig. 1. Here we see massive amounts of soil being lost due to the combined erosive forces of slope and water. This is an excellent example of the stresses, and the results of these stresses, placed on systems. Soil loss at this rate is dramatic, but losses at levels much lower than this can render a practice unsustainable. It is a rare agricultural system that is not losing soil at some rate, and any loss of soil is enough to render agriculture unsustainable.

The loss of soil can be easily seen and measured. By contrast, determining the health of the soil as an indicator is much more complex. Changes in pH, organic matter, nitrate leaching, salinization, heavy metals and pesticide accumulation, compaction, and general fertility are just some of the indicators used to determine soil health. Many of these indicators also have confounding effects on the others. For example, as soils become more acid certain metals, such as aluminum, are released.

The interaction of these items with biotic soil factors then complicates the equation even further. As complex as it is, the measure of soil health should be considered the main indicator of sustainability. All nonaquatic agricultural systems rely on this slow-to-build, rapid-to-degrade resource. In fact, nearly all agricultural soils can be viewed as degraded. Indicators then must measure improvements, rather than stability, if a system is to be deemed sustainable.

Biotic Indicators

Species diversity and the relative frequencies of butterflies, spiders, true bugs, and earthworms have all been used as indicators of sustainability. Earthworms (Fig. 2) are especially well suited to a role as indicators. More than 3500 species of earthworms exist, they are easy to capture and sort, and they are slow to recolonize. Slow
Fig. 1  Erosion of winter wheat field near Pullman, Washington. Photo by Stephen Jones, Original Data. (View this art in color at www.dekker.com.)

Fig. 2  Many species of earthworms are usually found in individual fields. Each may have different tolerances and susceptibilities to biotic and abiotic pressures. Photo courtesy of Mary Fauci, Washington State University. (View this art in color at www.dekker.com.)
recolonization is beneficial in an indicator because the shifts in populations can be more easily studied as they rise and fall over time. Species that recolonize rapidly may cause sampling problems, because rapid shifts may be missed if sampling is infrequent.

As early as the 1600s, earthworms were used as a measure of soil fertility. Today, they are a simple and economic measure of soil life. Individual species vary in their sensitivity to pesticides, tillage, moisture, soil structure, salt, heavy metals, predation, and many other relevant aspects of soil ecology. Paoletti lists 16 unique situations in which earthworms have been used to measure sustainability. The uses range from detecting archeological pesticide residues to comparing soil health at a landscape level in rural and urban interfaces.

Buckerfield et al., using four species of earthworms in southern Australia, showed a significant inverse relationship between intensity of tillage operation and earthworm abundance. They also recorded a significant correlation between crop productivity and earthworm abundance. They warned, however, that diverse crop management practices and cropping histories over time and space might make simple relationships between earthworms and productivity tenuous. With this in mind, they concluded that on an appropriate scale earthworm communities are useful as indicators of crop sustainability.

Crop and livestock diversity can also be used as indicators of sustainability. Ratios of annuals to perennials, permanent pasture to annual crop, and pest plants and animals to useful species may also indicate sustainability.

Aboveground diversity can be highly changeable, however. An individual farmer can go from a total monoculture system to intercropped multiline with perennial borders in a single season. The most important question of crop and animal diversity, therefore, is not if it is here today, but rather, if it will be available tomorrow. The use and availability of plant and animal varieties bred for long-term sustainability is an important indicator of the long-term health of sustainable systems. Where will farmers get seed and livestock that will be appropriate for sustainable agriculture in the future? Will the biodiversity be available? Will improved varieties be available to the farmers for a reasonable cost?

A MORE HOLISTIC APPROACH TO INDICATORS

Ecological indicators must be combined with economic and other factors when evaluating sustainability. Some also think that they should be viewed over an entire landscape rather than used as a single-field or farm measure. Di Pietro points out that traditional agriculture leads to simplification and that, in general, systems that use simplification as a style are poorly adaptable, and thus not sustainable. Working in the central Pyrenees of France, Di Pietro studied two holistic indicators: 1) the contributions of a field’s environmental features to land use choices (i.e., is sloping ground used for pasture or for crops), and 2) the diversity of environmental resources used by farms. The study was performed in two separate valleys. One was organized as a single unit of many farms, and the other as many units of individual farms and fields. Di Pietro showed that decisions at a landscape level are needed for sustainable measures to be effective.

Kemp et al., however, state that indicators at a farm level should be emphasized, because it is only at this level that environmental management can be applied effectively. This may be true today, but sustainability must eventually get past the single-farm level as the basic unit and move up to landscape levels and beyond. Nonpoint sources of influence, usually detrimental, are all too real in today’s agriculture.

CONCLUSION

Ecological indicators can be as simple as soil erosion or as complex as the availability of biologically diverse domestic crops and animals. To be effective, indicators should be used in concert with other relevant measures of sustainability. And as with the components of all models, indicators should be used with the caution that they are only as good as the inferences on which they’re based. For example, it is common to find biological indicators of sustainability based on yield and other measures of productivity. Short-term levels of high productivity can be based on unrealistically high amounts of imported inputs. To sustain these levels of production in most cases requires a highly extractive system. The result is anything but sustainable. Once systems have been deemed sustainable, then production would be a valid choice of indicator. Prior to that, though, the choice is ill-timed.

Sustainable Agriculture: Philosophical Framework

Paul B. Thompson
Michigan State University, East Lansing, Michigan, U.S.A.

INTRODUCTION

Several different philosophical frameworks are currently being deployed in developing programs and research projects for sustainable agriculture. Although the choice of a framework may depend on the aims and interests of those who develop these projects, it is important to be clear about the various ways in which sustainable agriculture is conceptualized. Successful programs and projects depend upon agreement about the basic meaning of sustainability in agricultural food systems.

APPROACHES TO SUSTAINABLE AGRICULTURE

The adjective “sustainable” implies that the activity it modifies can continue, if not indefinitely, then for some foreseeable and generally accepted period of time. Hence “sustainable agriculture” should simply indicate ways of producing standard agricultural food and fiber goods that can continue to be practiced for the foreseeable future. But this formulation is both vague and ambiguous. Underlying assumptions, methods, and values for sustainable farming practices and for research undertaken under the rubric of sustainable agriculture have been debated ever since the term came into wide usage in the 1980s.

The primary source of disagreement can be traced to an ambiguity in the basic idea of a sustainable practice that has led to two conflicting fundamental philosophical orientations. To say that an activity can be continued indefinitely is, on the one hand, to predict or estimate the feasibility of undertaking the activity over a future period of time. On the other hand, it may also be understood to mean that the activity should be allowed to continue in the future. This ambiguity has led to two incompatible schools of thought about sustainable agriculture.

In emphasizing prediction and measurement the first approach allows one to draw upon principles and methods developed in the agricultural sciences, as well as for such diverse areas as sustainable development, sustainable structural design, and sustainable urban planning. In this approach articulation of these principles and methods becomes critical to the conceptualization of sustainable agriculture. The alternative view is to understand sustainable agriculture in terms of pluralistic values and social interests that derive coherence from their mutual opposition to a perceived status quo. Advocates of this approach do not typically seek to clarify or unify their understanding of sustainable agriculture in terms of scientific principles. However, they might support the creation of research that would support and further the values and social interests to which they are committed.

SUSTAINABILITY AS A RESEARCH PROBLEM

There is disagreement even among those who have attempted to articulate scientific criteria for sustainability. In one of the first systematic attempts to specify the guiding principles of sustainable agriculture, Gordon Douglass[1] identified three distinct schools of thought: resource sufficiency, or the view that the resources needed to carry out a farming practice are on hand or foreseeably available; ecological, or the view that practices must not disrupt natural biological processes integral to the renewal of organic materials; and social, or the view that farming must be compatible with principles of justice and economic opportunity. Advocates of accounting principles to audit available resources understand sustainable agriculture in terms of resource sufficiency, in much the way that Douglass originally proposed. Other approaches can be categorized as stressing the functional integrity of systems. These can include both ecological and social dimensions of the food system; hence these approaches encompass elements of both ecological and social sustainability.[2]

Resource sufficiency has the advantage of suggesting specific quantitative and auditable measurements. The current stock of available resources can often be measured or estimated, and the rate at which resources such as soil, water, fossil fuel energy, and other inputs are being both consumed and resupplied can be calculated. These basic measures can be made more dynamic with models that estimate fluctuations in climate and the evolution of pathogens, or that predict the rate at which insects become resistant to given control strategies. In principle, it is even possible to incorporate changing economic incentives for producers into such models as the relative costs of various...
inputs shift due to increasing scarcity and policy changes. A full integration of such modeling techniques would produce a comparative measure of the relative sustainability of alternative production systems, and an indication of where strategic vulnerabilities may be thought to lie.

However, one weakness of the resource sufficiency approach is that its measure of sustainability is only as good as the data and the accuracy and completeness of the models used to assess the availability and rate of use for critical resources. Furthermore, some of the greatest strategic vulnerabilities of a given farming system may in fact be associated with the most difficult modeling and auditing challenges. What is more, social factors ranging from farm bankruptcy to policy changes and shifting consumer tastes clearly have great influence on producers’ ability to continue utilizing any given farming practice over time, yet the underlying processes governing such social changes are so complex that most have never been modeled.

This weakness in the resource sufficiency approach is, in part, why more qualitative conceptualizations that stress the way that various elements of a food and farming system are integrated have proliferated. The theme of functional integrity is that a set of practices or a farming system is sustainable when it is comparatively invulnerable to internal threats. Many of the accounting approaches utilized in measuring the sufficiency of resources reveal threats to the integrity of an agricultural or food system, but stressing functional integrity provides a philosophical framework that points toward a more holistic system and subsystem analysis. Two kinds of qualitative or philosophical value judgment are critical to the formulation of functional integrity. First, one must define system boundaries. Second, one must identify key strategic vulnerabilities.

System boundaries are critical to any conceptualization of sustainability, though boundary judgments are often implicit. The example of climate change illustrates why. Consider a case in which a local farming area suffers from dramatic climate change induced by industrial emissions of greenhouse gases. Drought conditions become commonplace, perhaps, or rising sea levels flood arable lands. Does this imply that the agriculture formerly being practiced there was unsustainable? Most would say not, and the reason is that they have implicitly accepted a boundary condition: Adverse affects on an agricultural system owing to industrial pollution do not count against the sustainability of the system. The industrial emissions certainly threaten the agricultural practice, but this is seen as an external threat—a threat coming from a source outside the system.

Incompatible boundary judgments give rise to disagreements about the sustainability of a given agricultural practice. This may occur especially when biologically trained individuals implicitly assume that all types of social causality are outside the system of interest. This kind of assumption may reflect the classical biologically oriented training of many agricultural researchers, who conduct laboratory research and field trials under conditions in which socioeconomic variables are controlled. Yet for any number of real-world applications, it is clearly the interaction of socioeconomic and ecological factors that will determine whether a system can continue to function under existing conditions.

Sometimes a single social criterion (such as profitability) is taken to determine sustainability irrespective of ecological factors. Here the problem may not be a disagreement about system boundaries, but may reflect implicit linkages between social and ecological system components that are simply being taken for granted. For example, some may assume that increasing scarcity of resources will be reflected in input costs, making profitability an adequate proxy for many ecological system elements. However, this assumption is itself based upon characteristics of policy and market structure that may or may not be reflected in the system of interest. In such instances, it is critical to articulate key vulnerabilities in qualitative terms, and to develop agreement among all participating parties about them.[3]

The need for agreement among those who participate in a sustainable agriculture has led some to argue that sustainability always implies a commitment to democracy. This may simply reflect the assumption that sustainable agriculture is a social movement rather than a researchable topic, but as a component of the feasibility of continuing any agricultural practice, democracy is a situation-specific element of sustainability, at best. In complex systems with many participants, the functional integrity of the system may depend upon including all relevant actors in decision making, and upon conducting decision-making processes in a democratic way. However, if the system of reference is a farmer’s field, and the key threats are ecological in nature, democracy may not figure importantly in the operational criteria for sustainability. In general, the specific criteria for functional integrity will vary widely depending upon the system of reference and its boundaries.[3]

**SUSTAINABILITY AS A SOCIAL MOVEMENT**

An alternative approach has been to see sustainable agriculture purely as a social movement. Deriving in some respects from Douglass’s idea of social sustainability, Patricia Allen and Carolyn Sachs[4] have argued that sustainable agriculture should be understood as a banner for interest groups seeking political change. In this view,
one should not seek the principles that make agriculture sustainable, but should see the term as a convenient label for politically aligned interests. The interest groups associated with the term often include farm labor, women, consumer groups, small-farm groups, and advocates of animal welfare.

Although this approach to sustainable agriculture is clearly normative, the norms advocated are broad and not necessarily compatible. Sociologists Curtis Beus and Riley Dunlop[5] offer a complex portrait of competing agricultural paradigms. Sustainable agriculture is portrayed as an alternative to the conventional status quo on each of 27 points, summarized in 6 categories: decentralization, independence, community, diversity, restraint, and harmony with nature. To the extent that these points reflect a normative commitment to opposing conventional or industrial agricultural methods, they can be said to reflect a philosophical framework for sustainable agriculture.

CONCLUSION

The choice of a philosophical framework for approaching sustainable agriculture may reflect the specific interests and capabilities of the individuals undertaking a sustainable agriculture project. However, the opportunities for disagreement and misunderstanding are great, and it is always wise to be as explicit in articulating this framework as one possibly can be.

Sweet Sorghum: Applications in Ethanol Production

Glen C. Rains
University of Georgia, Tifton, Georgia, U.S.A.

John W. Worley
University of Georgia, Athens, Georgia, U.S.A.

INTRODUCTION

Ethanol demand is currently over 1.8 billion gallons per year and estimated demand is expected to grow at an annual rate of 1.7 percent through the year 2020.[1] Although corn will continue to be the primary feedstock for ethanol, several biomass crops have been investigated for their merits as an ethanol feedstock. Sweet sorghum is an annual crop that has an excellent yield of fermentable sugars, is resistant to drought and adaptable to poor soils, and can thrive in a wide range of climates. It has been found that in certain geographical regions, such as the U.S. Piedmont (a geographical region spanning 170 counties from Virginia to Alabama), sweet sorghum produces more carbohydrates per hectare than corn, and would not directly compete in the food market. However, a system that economically produces and processes sweet sorghum for ethanol production has yet to be developed. This article discusses three systems of sweet sorghum for ethanol production in the U.S. Piedmont, and future developments that could make sweet sorghum an economically viable ethanol feedstock.

CONVERSION OF SWEET SORGHUM TO ETHANOL

The sweet sorghum stalk contains approximately 94% of the total soluble sugars (TSS) in the plant; about 85% of the TSS are located in the stalk pith fraction inside the stalk. Consequently, ethanol production has been examined in terms of both juice expression from whole stalks and pith fraction after separation from the rind and leaf fraction (rind-leaf). Crandell et al.[2] compared juice and sugar expression efficiencies from chopped whole stalks with those from the pith fraction after processing to remove most of the stalk rind and leaves. They found that juice expression as a percentage of whole stalk mass increased from 36 to 45% when the pith was first separated from the rind-leaf fraction. In the same experiment, sugar expression increased from 44 to 61% of whole stalk sugars from the separated material.

POTENTIAL SYSTEMS FOR PROCESSING SWEET SORGHUM FOR ETHANOL

Three systems for sweet sorghum harvesting and processing to produce ethanol have been analyzed.[3] The three systems are referred to as the forage chopper system, pith combine system, and Piedmont system (Fig. 1). The forage chopper system is characterized by harvesting sweet sorghum with a commercially available forage chopper and transporting the chopped stalks to a screw press parked next to or inside a bunk silo. The stalks are fed to the screw press for juice extraction and the residue (presscake) is conveyed into the silo. The ensiled presscake can be utilized for cattle feed, or taken to the fermentation plant for fiber breakdown and conversion to sugars for ethanol.

The pith combine system uses a modified forage chopper that chops the forage and then separates the pith (sugar fraction) from the rind-leaf (fiber fraction) using a straw-walker mechanism.[2] The rind-leaf is left on the field and the pith fraction is transported to the silo. The pith fraction is then fed into the screw press and the presscake conveyed into the bunk silo. By separating the rind-leaf fraction from the pith, screw-press efficiency and capacity are increased. The presscake is then ensiled for cattle feed or for further cellulose breakdown into sugars as in the forage chopper system. The rind-leaf can also be baled for hay and fed to cattle, stored and processed later to break down the cellulose into sugars, or left on the field to increase soil organic matter. The third system is the piedmont system. This system requires the highest capital investment because the harvesting and processing of the sweet sorghum is conducted with a dedicated machine that must be purchased or rented from a contractor who harvests and processes sweet sorghum on a custom basis. The piedmont system operates as follows: A whole-stalk harvester cuts stalks at the base and lays them in continuous windrows around the field. A field loader then loads stalks onto a trailer for transport to a storage facility near a bunk silo. Because the stalks are kept whole and intact, they can be stored 30 to 60 days without substantial loss in fermentables.[4] Stalks are loaded into a
mobile processor that consists of a feeder, chopper, and pith separator (straw-walker). The pith separator separates the pith from the rind-leaf. The pith is entered into the screw press to express the juice, and the pith presscake is then recombined with the rind-leaf fraction and conveyed into the bunk silo. The presscake and rind-leaf can be handled as cattle feed or as future feedstock for ethanol.

In each system, juice from the screw press can be directly delivered to the fermentation/distillation plant for production of ethanol, or to an evaporation plant where the juice is concentrated into syrup for storage and later carried to the fermentation plant for ethanol production.

**ECONOMIC CONSIDERATIONS**

Limited data indicate that the expression ratios (mass of juice as a fraction of whole stalk mass) for the screw press using the three systems are 0.35 (forage chopper), 0.45 (pith combine), and 0.55 (piedmont system). An increased expression ratio increases screw press performance and decreases the cost of operation. The piedmont system requires the greatest capital investment and the forage chopper system the least. An important economic consideration is the ability of the piedmont system to store the fermentable sugars in the whole stalk, extending the processing window beyond the harvest season. (Equipment breakdowns do not immediately endanger the processing because stalks can be processed whenever the equipment is ready.) The forage chopper and pith combine systems must either ferment or distill the juice before it begins to sour. A systems model\(^5\) examined the cost of production of each system of sorghum harvesting and processing, and indicates that transportation contributes significantly to the cost of production, especially when moving the by-products for further ethanol production. The model shows that the pith combine system is the cheapest per Mg whole stalk, whereas the piedmont system is the most expensive. All three systems are too expensive to make a profit without government subsidies.

Each system has options for processing the sweet sorghum once it is separated into juice, presscake from the screw press, or rind-leaf fractions (Fig. 1). Juice can be sent to a fermentation/distillation plant for direct conversion to ethanol. In this case, sweet sorghum by-product (materials placed in the bunk silo) can be transported to the plant later, after harvest season peak demand, and be converted to sugars for further ethanol production. A recent study indicates that one or more microorganisms can carry out simultaneous hydrolysis and fermentation of cellulose to ethanol in the same bioreactor.\(^6\) If the by-product is useful as a cattle feed, part of the juice can be sent to an evaporation plant to be concentrated into syrup and stored for processing until peak demand for the fermentation/distillation plant concludes.

Other by-product uses such as source of heat energy, pulp for fiberboard manufacture, hay for animal feed, and organic matter for field amendments are important in determining the economic viability of sweet sorghum for ethanol production. By-product value is difficult to estimate. Based on a model by Worley et al.,\(^7\) the by-product
values depend less on the system chosen to produce ethanol than on the intended use of the by-product. The highest value is assigned to by-product silage used as cattle feed on the grower’s own farm. Fiber conversion to obtain further ethanol production yields the lowest value. However, this study did not consider some of the newer techniques for bioconversion of presscake that show a yield of 5.1 g ethanol per 100 g of fresh stalks.\(^6\)

**CONCLUSION**

Sweet sorghum research is in its infancy relative to research on other biomass crops such as corn and sugarcane. As such, it is highly likely that increases in biomass production can be achieved through development of improved genotypes. Studies continue on the use of sweet sorghum as an energy source through conversion to ethanol or electricity.\(^{[6,9]}\) Developing more uses for by-products and improved production practices seem to hold promise for improving the economic viability of sweet sorghum.

Sweetgrass and Its Use in African-American Folk Art

Robert J. Dufault
Clemson University, Charleston, South Carolina, U.S.A.

INTRODUCTION

Sweetgrass (*Muhlenbergia filipes*) is the main structural material used in African-coiled basketry. The plant is a native, perennial, warm-season grass found growing sparsely along the ocean in narrow bands between coastal sand dunes from North Carolina to Texas. Much of the native sweetgrass groves have been lost in the region due to oceanfront development. The continuance of this old African-American folk art is jeopardized by the loss of sweetgrass. Since the late 1980s, horticultural research has determined that sweetgrass can be grown successfully as a row crop, but the plant is a short-lived perennial, needing replanting every four years to maintain supply. With knowledge of how to propagate and cultivate sweetgrass, sweetgrass “gardens” could be planted in the backyards of individual basketmakers to finally solve the supply problem.

SWEETGRASS BASKETS

The city of Charleston, South Carolina, was founded in 1670 and is bedazzled with lovely old homes and gardens throughout its old and winding streets. However, even older than most homes in Charleston is the ancient tradition of sweetgrass basketmaking. The significance and legacy of producing these historic baskets has been a treasured, beloved birthright held dear by generations of basket makers, the direct descendants of enslaved Africans of plantation days. About 30 years ago, approximately 1200 families were involved in basketmaking, but now only about 300 families are involved in the tradition (personal communication with Mary Jackson, past president of Mt. Pleasant Basketmaking Association). The most insidious factor contributing to the demise of this folk art is the gradual loss of natural sweetgrass habitats in the region. Sweetgrass once was readily available and abundant in the Charleston area, but today sweetgrass is very scarce and difficult to find.

Sweetgrass (*M. filipes*), the main structural material used in African-coiled basketry, is a native, perennial, warm-season grass found growing sparsely along the ocean in narrow bands between coastal sand dunes from North Carolina to Texas. The narrow leaf blades are harvested green and dried before use in sweetgrass baskets. Successive coils of sweetgrass are sewn together in rows, not woven, with strips of leaf material from the palmetto tree (*Sabal palmetto*), the state tree of South Carolina. The explosion of growth in the Charleston area by new residents and industries has caused a boom in urban and beachfront development to support the demand by the growing population. Urbanization has destroyed much of the natural habitats of sweetgrass, as has development of beachfront communities on the barrier islands off the coast of Charleston. Basketmakers now have to travel hundreds of miles to Georgia and Florida to find adequate supplies. Many basketmakers are old and these long, expensive, arduous trips are impossible and frustrating, which has fueled the loss of basketmakers (Fig. 1).

The roots of the sweetgrass basket craft were born out of slavery. Colonial Charleston was a very prosperous city built on many agricultural industries beginning with rice in the late 1600s and early 1700s, then indigo, and lastly cotton. With Charleston’s warm climate, a long growing season, and extensive marshy wetlands, the area was a natural for growing the lucrative rice crop. Rice was a staple crop in Africa, and Africans had cultivated rice for centuries and perfected its production. Slavers identified these people, the ancestors of today’s Low Country basketmakers, and abducted them into the slave trade for use on rice plantations in the New World.

The enslaved Africans brought the expertise to produce rice from the planting, harvesting, and processing. African-coiled basketry was critical in the processing of the rice. With flat fanner sweetgrass baskets, the seed was thrown into the air to separate the rice seed from chaff. Slavers were paid premium price for Africans from the West African Rice Kingdoms of the Windward Coast (Senegal to the Ivory Coast) to the mouth of the Congo River (Gabon, Zaire, and Angola). A man or woman who made baskets was worth more than one who did not, with age, strength, and other skills being equal. History has not fully credited the enslaved African for the success of the rice kingdom in the South, but without their knowledge of the crop cultivation and processing, rice would have never flourished. Besides fanner baskets, enslaved Africans sewed all sorts of utilitarian vessels to hold and store agricultural commodities and to use in...
Sweetgrass basketry is one of the earliest traditional crafts with a rich documented history from “carryover” from African enslavement and colonial plantation days to the present. These African skills remained unchanged and have been passed down from generation to generation for over 300 years from parents to siblings. Though the raw materials are different in American and African baskets, amazingly the construction techniques of sweetgrass baskets are unchanged from their African counterparts to this day. Some American basketmakers have journeyed to Senegal, Africa, and have reported very similar baskets and techniques still produced by today’s African basketmaker. Modern basketmakers in the Low Country of South Carolina have introduced a multitude of new basket forms and functions, which are still very useful in the home, but these baskets are now considered “objects of art” more than just utilitarian baskets of old.

To basketmakers, sweetgrass basketry symbolizes 1) their heritage and connection to their African ancestry and 2) a remembrance of people who survived centuries of oppression. They have made a reaffirmation of these goals with each new generation with sweetgrass basketry representing the heart and keepsake of their devotion.

Basketmakers have always wondered if they could cultivate sweetgrass inland similarly to vegetables, but individual attempts to transplant the plant were not successful. By 1988, the plight of the basketmakers was common knowledge due to timely newspaper articles. In 1989, I became intrigued with the idea of domesticating sweetgrass and became involved in attempts to learn how to grow it in a cultivated state. After four years of part-time trial and error using many different horticultural approaches and techniques, in 1993 I felt confident to plant a large experimental planting somewhere in the Low Country. The Historic Charleston Foundation offered land at the old McLeod Plantation for our field trials. Established in 1947, the Historic Charleston Foundation is a nonprofit educational organization dedicated to historic preservation. McLeod Plantation, now owned by the Historic Charleston Foundation, is the last intact plantation on James Island and a historic landmark. So, with enthusiasm, members of the Mt. Pleasant Basketmakers Association and I toiled to prepare and plant 2000 sweetgrass plants in an effort to eventually eliminate the shortage. A second acre was planted at McLeod, and in May 1995 two more acres were planted. Many other important benefactors joined us to help support our goal of ending the sweetgrass shortage problem, such as the City of Charleston, the Agricultural Society of South Carolina, the SC Seagrant Consortium, and the Trident Community Foundation. We enlisted the assistance of the National Civilian Community Corps to help prepare and plant the expansion acreage in 1995. By summer 1995, we had four acres of sweetgrass maturing for harvest within two years.

The year of 1995 was a historic year for the basketmakers, as the first acre of sweetgrass at McLeod was finally mature enough for extensive harvesting. In past years, the plants were rather succulent and brittle, which rendered the cultivated grass unsuitable for basketry. However, in 1995, the plants matured and grew into very large clumps. Plant competition caused the leaves to lengthen and become very strong and fibrous, which are critically important characteristics of high-quality sweetgrass for basketry. By midsummer, we finally knew that our grand experiment of cultivating sweetgrass at McLeod was a rousing success. Basketmakers judged the quality of the cultivated sweetgrass excellent for basketry. The downside of this grand experiment was twofold: 1) Sweetgrass in cultivation was found to be a short-lived perennial, and earlier plantings only lived for about four years and then declined by 1998; and 2) maintenance of such large acreage by basketmakers was too difficult for the community to handle. It appeared that large plantings were not the best approach to solve the supply issue.

CONCLUSION

During the years I worked with this crop, I learned many secrets about the plant’s growth and development. Although the supply problem still plagues the basketmakers, we now know the horticulture of this plant. I feel that the supply problem can be solved easily by individual basketmakers establishing sweetgrass plantings in their own backyard. A 25’ by 25’ plot would probably
sustain the needs of a basketmaker or two. The plant thrives on benign neglect and doesn’t require any fertilizer or much water during the growing season. This scheme would provide a free product to supply individuals who would take responsibility and pride in not only producing a beautiful art object but also growing the “basket” from seed.

Switchgrass As a Bioenergy Crop

Samuel B. McLaughlin
Lynn A. Kszos
Oak Ridge National Laboratory, Oak Ridge, Tennessee, U.S.A.

INTRODUCTION

The production of renewable bioenergy from crops grown on American farms to supplement fossil-derived energy sources could provide the United States with many desirable ecological and economic benefits. These include reduced dependency on imported oil and its associated geopolitical and economic risks; reduced damage to sensitive ecosystems associated with the high ecological costs of fossil fuel mining/recovery; reduced emissions of both greenhouse gases and toxic air pollutants associated with combustion of fossil fuels; and increased economic benefits to American farmers who would produce and harvest the renewable energy embodied in crops or crop residues.

Among the many types and sources of renewable energy—which include solar, wind, water, municipal waste, and agricultural residues—perhaps the greatest potential for ecological and economic gains to the agricultural industry is from dedicated energy crops. Dedicated energy crops include short-rotation woody crops as well as annual or perennial herbaceous crops grown specifically for energy industries. These are potentially very attractive to industry because they can be selected to provide desirable feedstock chemical and physical attributes, and can be planted in close proximity to industrial sites to assure adequate supply of feedstock of acceptable quality with reduced transportation costs. Among the potential dedicated energy crops, switchgrass (Panicum virgatum) was selected by the U.S. Department of Energy–sponsored Bioenergy Feedstock Development Program (BFDP) in 1991 as a model herbaceous species for research and development based on the relatively low energy and resource requirements associated with high-yield capacity, its ecological value in protecting and improving soil quality and wildlife habitat, and its compatibility with conventional farming equipment and management practices.

Switchgrass has been planted as a forage grass in the great plains for over 50 years and is one of the principal grasses planted to restore soil quality in the U.S. Conservation Reserve Program. As a species for bioenergy production, the criteria for successful development shifted toward maximum production of biomass and associated cell wall constituents (such as cellulose that could be converted to fuels such as ethanol, or combusted to produce heat and electricity). In addition, achieving low mineral content in harvested biomass is important in reducing mineral buildup during combustion or conversion processes. Thus, high yields and low mineral nutrient content became relatively more important in selecting, improving, and managing switchgrass as a bioenergy species. This represents a shift in focus from the criteria for traditional forage production for animal consumption, where high mineral nutrient content and low stem:leaf ratios are more desirable attributes.

The past 10 years of BFDP research have focused on strategies for efficiently establishing and managing switchgrass for maximum biomass production; defining and improving breeding techniques to maximize biomass rooting pattern that equips it to thrive in a wide variety of habitats and soils that are unsuitable for many types of row crops. Switchgrass formed an important component of the original tall-grass prairie in the central United States. Much of the original prairie habitat has been converted to cropland, and switchgrass can currently be found in more thinly dispersed and smaller stands in diverse habitats. These include both grasslands and open forests in North America east of the Rocky Mountains. Two main ecotypes occur naturally in this genetically diverse, open-pollinated species: 1) lowland ecotype, that is thicker-stemmed and adapted to warmer, moister sites in the South; and 2) an upland ecotype that has thinner stems and is adapted to somewhat drier soils and cooler climatic conditions. Switchgrass was chosen as a model herbaceous bioenergy crop for research and development based on the relatively low energy and resource requirements associated with high-yield capacity, its ecological value in protecting and improving soil quality and wildlife habitat, and its compatibility with conventional farming equipment and management practices.

ECOLOGICAL AND AGRONOMIC ATTRIBUTES OF SWITCHGRASS

Switchgrass is a perennial bunch grass native to the United States. It has the highly efficient C4 carbon metabolism typical of warm season grasses and a deep rooting pattern that equips it to thrive in a wide variety of habitats and soils that are unsuitable for many types of row crops. Switchgrass formed an important component of the original tall-grass prairie in the central United States. Much of the original prairie habitat has been converted to cropland, and switchgrass can currently be found in more thinly dispersed and smaller stands in diverse habitats. These include both grasslands and open forests in North America east of the Rocky Mountains. Two main ecotypes occur naturally in this genetically diverse, open-pollinated species: 1) lowland ecotype, that is thicker-stemmed and adapted to warmer, moister sites in the South; and 2) an upland ecotype that has thinner stems and is adapted to somewhat drier soils and cooler climatic conditions. Switchgrass was chosen as a model herbaceous bioenergy crop for research and development based on the relatively low energy and resource requirements associated with high-yield capacity, its ecological value in protecting and improving soil quality and wildlife habitat, and its compatibility with conventional farming equipment and management practices.

Switchgrass has been planted as a forage grass in the great plains for over 50 years and is one of the principal grasses planted to restore soil quality in the U.S. Conservation Reserve Program. As a species for bioenergy production, the criteria for successful development shifted toward maximum production of biomass and associated cell wall constituents (such as cellulose that could be converted to fuels such as ethanol, or combusted to produce heat and electricity). In addition, achieving low mineral content in harvested biomass is important in reducing mineral buildup during combustion or conversion processes. Thus, high yields and low mineral nutrient content became relatively more important in selecting, improving, and managing switchgrass as a bioenergy species. This represents a shift in focus from the criteria for traditional forage production for animal consumption, where high mineral nutrient content and low stem:leaf ratios are more desirable attributes.

The past 10 years of BFDP research have focused on strategies for efficiently establishing and managing switchgrass for maximum biomass production; defining and improving breeding techniques to maximize biomass
production potential; and basic studies to better understand the underlying genetics, physiology, and soil–carbon cycles of switchgrass grown as an energy crop. More recently, integrative assessments have evaluated the potential of switchgrass to contribute ecological and economic gains as a component of a national energy strategy.

ESTABLISHING AND MANAGING SWITCHGRASS

One of the principal challenges of producing switchgrass lies in successful establishment of this light-seeded perennial species, which typically attains less than a third of its full production potential during the first year. Because of slow growth in the establishment year, switchgrass typically takes 2–3 years to attain full production capacity. Planting seed of known viability in a firm seedbed, controlling weeds during the initial year, and restricting cutting practices to 1–2 cuts per year are important considerations in maximizing switchgrass production. There are several pre- and post-emergence herbicides available for use on nongrazed grasses, including Plateau®, Paramount®, Roundup®, and atrazine. However, the success of these herbicides and appropriate dosage rates can vary regionally, and latitude should be considered in designing an optimum weed control plan. Higher temperatures in Texas, for example, can increase the toxicity of some herbicides to switchgrass.

Growing within its zone of natural adaptation, switchgrass has very high resistance to foliar diseases, although there has been increasing evidence of leaf diseases on some varieties in larger plantings in the Midwest in recent years. Recently initiated research also suggests that nematodes play some role in inhibiting growth of switchgrass during the establishment year. More research is needed in this area, as important gains in early establishment might be realized from improved understanding of the role of belowground diseases.

Production management research within BFDP has focused on identifying the most productive existing cultivars, their regions of optimum adaptation, and the management practices that optimize production efficiency within the regions. The best commercial varieties determined by 10 years of production in field research plots are the lowland variety Alamo, in the deep South; the lowland varieties Alamo and Kanlow at mid-latitudes; and the upland variety Cave-in-Rock for northern latitudes. Yield of the best adapted varieties averages 15–22 Mg ha⁻¹ y⁻¹ in regional field trials. Yields of currently available varieties in production-scale fields are expected to be 30% lower, around 10–15 Mg ha⁻¹ (4.5–7 tons ac⁻¹). Lowland varieties produce highest yields in the deep South, with either a single harvest in late August to mid-September, or two harvests with early July and November target dates. Upland varieties such as Cave-in-Rock may, under the best growing conditions, achieve yields comparable to lowland varieties in the South, but clearly require two harvests annually to attain those yields. In Alabama, row spacings may be increased to as much as 80 cm without yield loss. The combination of flexible harvest frequency and timing is attractive to landowners who are managing multiple crops, whereas the row spacing flexibility improves potential attractiveness of switchgrass stands for game bird cover. From the perspective of resource utilization efficiency, the single-cut system offers higher returns based on reduced energy inputs associated with a single harvest and substantially lower nutrient removal. Nitrogen is the only nutrient that consistently stimulated switchgrass yields, and nitrogen removal has been reduced by approximately 60%, to 30–50 kg N ha⁻¹, with single-harvest systems. Recommended N application rates are 50–100 kg N ha⁻¹ y⁻¹ in most areas; however, there is some evidence that switchgrass stands may become less dependent on external nitrogen as internal sources in roots, crowns and soil organic matter accumulate.

DESIRABLE PRODUCTION CHARACTERISTICS

Production characteristics of primary interest in selecting a bioenergy crop are high yield potential, low yield variability over time in the face of variable environmental conditions, the persistence of the stand over time, and the quality of the feedstock produced. The longest continuous yield plots in the BFDP system were planted to Alamo switchgrass in 1988 and have shown high yields (13 yr avg = 23 Mg ha⁻¹) and an apparent increase in resistance to drought (Fig. 1) over time. Whereas irrigation has not been considered a desirable management option for energy crops, experience in Texas suggests that a single midseason irrigation event may double switchgrass yields in dry years. The potential sharing of irrigation equipment among multiple fields for which only one or two irrigation events are required during the season increases the probability that irrigation would be an economically viable option for switchgrass. The capacity of switchgrass (as well as other warm season grasses) to maintain such high yields even during periods of infrequent rainfall can be attributed to its deep, well developed root system. In the mid-Atlantic states standing root mass has been found to be comparable to annual aboveground production.
High switchgrass root production and turnover are important not only in nutrient and water acquisition from soils but also in increasing soil organic matter (SOM). Studies across diverse soil types in both the mid-Atlantic region and in Texas have documented significant increases in SOM in soils under switchgrass.\(^\text{[5–7]}\) In the mid-Atlantic region, SOM increases ranged from 20% to 125%, and averaged 43% across eight study sites over a 10-year period.\(^\text{[6]}\) The accumulation of SOM with root production and turnover has important implications for improving water and nutrient retention and availability in associated soils. Such increases are also important in the net reduction of carbon dioxide emissions derived from the utilization of switchgrass as a renewable energy source.

**Fig. 1** Long-term yields of Alamo switchgrass from Auburn, Alabama compared to annual rainfall. Note the relative insensitivity of annual yields to the very low rainfall occurring in 2000. This stand was planted in 1988 and was harvested twice each year in early July and September. (Data from Ref. 7.)

**Fig. 2** Through production and turnover of fine roots, switchgrass can contribute significant amounts of soil organic carbon to the farm lands on which it is grown (POM-C = particulate organic matter, MOM-C = mineral-associated organic matter). Modeling studies indicate that these gains are influenced by soil temperature and prior accumulation of soil carbon ((a) cropland; (b) pasture) (MAT = mean annual temperature). (Prediction and analyses from Ref. 8.)
source. An empirically based model of soil carbon accumulation under switchgrass has been developed to estimate relative contributions of both labile and recalcitrant carbon to accumulated soil carbon under switchgrass over time (Fig. 2). The model projects annual accumulation rates that ranged up to 1.4 Mg C ha$^{-1}$ y$^{-1}$ over 10 years on degraded soils in warmer climates and averaged 0.78 Mg C ha$^{-1}$ y$^{-1}$ over 30 years across diverse regions in the U.S. East. Thus, carbon storage in soils under switchgrass can represent a significant contribution to total reduction in carbon emission achieved in utilizing switchgrass for bioenergy.

**BREEDING**

Breeding research with switchgrass over the past 10 years has contributed significant new knowledge to the basic breeding biology of switchgrass. Switchgrass has been found to typically occur in either tetraploid ($4x = 36n$) or octoploid ($8x = 72n$) multiples of the nine basic chromosome pairs. It is an open-pollinated, self-incompatible species, within which crossing across ecotypes does occur, although crosses between ploidy levels are rare. At present, germplasm derived from accessions from nine clusters that were delineated within a larger population of 115 accessions of switchgrass examined in the BFDP has been submitted to the U.S. Department of Agriculture’s National Plant Germplasm System. Early in the breeding effort with switchgrass, fast-track breeding approaches such as Recurrent Restricted Phenotypic Selection based primarily on first-year growth of switchgrass were replaced with a slower but more predictable genotypic selection process based on performance of test plants over at least 2 years, and quantitative evidence of high heritability of desirable agronomic traits from candidate parent plants. In addition, heterosis has now been demonstrated in switchgrass allowing a narrowly restricted breeding base to be used to target specific desirable traits. More than 15 experimental synthetics have been developed, at least three of which are undergoing performance verification for commercial release by seed companies. Expected genetic gains estimated from among half-sib families have been 5–26% above the best commercially available varieties; however, yield gains have also been shown to be strongly influenced by the test environment.

**EVALUATING SWITCHGRASS AS A BIOFUEL**

To be successful as a biofuel crop, a species like switchgrass must be physically and chemically acceptable as a fuel for industrial use as well as economically competitive in both agricultural and industrial markets. The chemical and physical attributes of switchgrass shown in Table 1 include a relatively high energy content combined with a relatively low ash content. These traits make switchgrass a desirable fuel, both for combustion to produce heat and electricity, and for conversion to ethanol as a transportation fuel. Estimates of the competitive potential of switchgrass as a crop in agricultural markets

(From Ref. 10.)
using an agricultural sector model indicate that at a price of $44 Mg\(^{-1}\), switchgrass would be more profitable than crops currently grown on approximately 16.9 million ha of American farmland.\(^8\) As reliance on energy from biofuels increases in the future, switchgrass should thus provide an economically attractive alternative cash crop for American farmers when priced at these levels. At present, switchgrass is not being utilized on a large scale for bioenergy production. However, pilot testing of switchgrass combustion characteristics and performance by research teams that have included two commercial power producers has been completed successfully. In addition, a large-scale power production system involving switchgrass produced on 8000 ha by a farmers’ cooperative is currently being developed and tested for full-scale operational feasibility in Chariton Valley, Iowa.

The value of a fuel for national energy supply should theoretically include not only its value as a source of energy, but also its impacts on society as a whole. Currently, research in the bioenergy industry is increasingly being directed toward producing not only energy and fuels from biomass, but also a wide variety of industrial chemicals that can add value to the bioenergy cycle. The development of capabilities to transform crops like switchgrass to improve production potential\(^1\) may lead to increased recovery of specific chemicals of industrial interest as well as improved production potential of switchgrass. The true value of bioenergy crops also encompasses ecological and agronomic values that are not traditionally considered in fuel prices. For this reason, life cycle analyses of switchgrass production have been conducted to consider some of these secondary values relative to current fossil fuel scenarios. Included among the effects of production of 16.9 million ha of switchgrass at $44 Mg\(^{-1}\) in the previous example were estimated annual increases of $6 billion in net farm revenues, $1.86 billion reduction in government subsidies due to improved farm income, and displacement of 44–150 Tg (1 Tg = 10\(^{12}\) g of carbon) emissions to the atmosphere.\(^9\) Benefits of this magnitude substantially reduce the societal costs of renewable biofuels relative to fossil fuels, and should provide economic incentives to expedite the commercialization of switchgrass as a bioenergy crop.

CONCLUSION

Production of dedicated energy crops on American farms represents a potentially important way to decrease America’s dependency on imported energy while providing significant economic and ecological benefits to the national economy. Research on management, breeding, and both ecological and economic benefits of a perennial native grass species, switchgrass, as a source of renewable energy suggests that this species could play an important role in the search for greater national energy self-sufficiency. Switchgrass can be used to produce electric power, transportation fuels, and biobased products. Benefits of developing a biobased economy with participation of America’s farmers as energy suppliers are substantial and include improved farm income, improved soil productivity and stability, reduced greenhouse gas emissions, and reduced need for government subsidies of crop prices.

Symbioses with Rhizobia and Mycorrhizal Fungi: Microbe/Plant Interactions and Signal Exchange

James E. Cooper
Queen’s University, Belfast, United Kingdom

INTRODUCTION

By virtue of their ability to capture (fix) atmospheric nitrogen, legumes assume a special significance among agricultural plants. Their productivity is theoretically independent of soil nitrogen status and they provide important grain and forage crops in both temperate and tropical zones. Nitrogen fixation can occur only when these plants are in the symbiotic state and the agents of fixation are soil bacteria, the rhizobia, which invade limited regions of the root cortex via infection threads in root hairs. Successful infections result in the development of root nodules, into which gaseous nitrogen diffuses to be reduced to ammonium by the nitrogenase enzyme of rhizobial bacteroids. An overwhelming majority of land plants, including most legumes, also form root symbioses with fungi, known collectively as mycorrhizae, which improve the supply of phosphate and other nutrients from soil to plant roots and confer increased resistance to plant pathogens. Most mycorrhizal associations can be allocated to one of two broad categories: the ectomycorrhizae, characterised by a fungal sheath and limited intercellular penetration of the root cortex of gymnosperms and woody angiosperms, or the endomycorrhizae, which possess hyphal structures that develop inside cortical cells of woody and herbaceous angiosperms. Arbuscules are examples of such structures; they are highly branched extensions of fungal hyphae that are common, though not ubiquitous, among the endomycorrhizae. Arbuscular mycorrhizal (AM) and rhizobial symbioses are similar in the sense that both are intracellular, but the former, involving the fungal order Glomales, is by far the more ancient of the two systems. In each case the progression to the symbiotic state is governed by reciprocal signal generation and perception, which may be viewed in terms of a “molecular dialogue” between the partners. While the early interactions between legumes and rhizobia are now largely understood at the biochemical and molecular genetic levels, details of events leading to the formation of mycorrhizal symbioses have not yet been elucidated.

PRIMARY SIGNALS FROM LEGUMES TO RHIZOBIA

In most examples studied to date, the first identified signals are flavonoids or isoflavonoids in legume root or seed exudates. These compounds are secondary metabolites of the plant phenylpropanoid biosynthetic pathway. (For examples of structural features, see Fig. 1.) Their main role in the initiation of a rhizobial symbiosis is an interaction with the constitutively expressed nodD gene product(s) of the microsymbiont to form a protein-phenolic complex: a transcriptional regulator of other rhizobial nodulation (nod) genes that are responsible for synthesis of reciprocal signals to the plant root. Different legumes release different compounds that act either as nod gene inducers or inhibitors for their specific rhizobia. The first symbiotically active flavonoid to be discovered was a flavone, luteolin, which is a nod gene inducer in the Medicago sativa/Sinorhizobium meliloti symbiosis.[1] Daidzein, an isoflavone, is an inducer in the Phaseolus vulgaris/Rhizobium leguminosarum biovar phaseoli symbiosis, whereas kaempferol, a flavonol, is an inhibitor in the Trifolium/R. leguminosarum biovar trifolii symbiosis. It is the relative proportion of inducing and inhibiting compounds in seed or root exudates that is thought to determine the overall level of nod gene induction in compatible rhizobia. Certain non-flavonoid compounds in legume root exudates also act as nod gene inducers: the betaines stachydrine and trigonelline from Medicago and the aldonic acids erythronic and tetrronic acid from Lupinus. However, unlike flavonoids, whose biological activity is expressed at nanomolar concentrations, these compounds elicit nod gene induction only at concentrations greater than c. 10 mM. The varying responsiveness to flavonoids of NodD proteins from different rhizobial species and biovars accounts for one of the elements determining the host specificity of these bacteria. For example, Sinorhizobium meliloti will form root nodules on alfalfa (Medicago) but not on clovers or soybean. Other responses of rhizobia to legume flavonoids that may be significant for
infection of the host plant include removal of glycosidic residues from flavonoid-sugar conjugates, degradation to yield new flavonoids and other, monocylic phenolics, positive chemotaxis to some nod gene inducers, and increased growth rates in nutrient-limited media supplemented with low micromolar concentrations of inducing or non-inducing compounds.

REVERSE SIGNALS FROM RHIZOBIA TO LEGUME ROOTS—THE CHITOLIPOLIGOSACCHARIDE NOD FACTORS

The combination of NodD proteins with appropriate plant flavonoids triggers the production of highly specific reverse signal molecules by rhizobia—the chitolipooligosaccharide (CLOS) Nod factors—by means of the transcriptional activation of common and host specific nod genes. The common nodABC genes are required for the synthesis of a chitinlike template, comprising several β1,4-linked N-acetyl glucosamine residues, which forms the basis of Nod factor structures found in all rhizobia studied to date. NodC is a β-glycosyl transferase that forms chitin oligomers and can influence host specificity of the Nod factor to some extent, depending on final chain length (2- to 6-mer). NodB deacetylates the terminal (non-reducing) glucosamine residue while NodA is involved in the transfer of a fatty acid moiety to this position. Fatty acids may be of the type common to bacterial phospholipids (e.g., C18:1), and chain length may vary even in Nod factors produced by a single bacterial species or biovar. In some rhizobia, nodFEG genes (which are usually classified as host-specific nod genes) are required for the formation of highly unsaturated fatty acids. An example of a typical Nod factor precursor template is shown in Fig. 2.

The major determinants of host specificity lie in the so-called “decorations” on the common CLOS template described above. Depending on the producing organism, acetyl, arabinosyl, carbamoyl, fucosyl, glycerol, mannosyl, methyl, or sulphate groups have been reported at various positions. In S. meliloti, whose Nod factor structure was the first to be discovered in 1990,[2] an acetyl group is introduced at the 6-C position of the nonreducing end of the CLOS molecule by an O-acetyl transferase encoded by the nodL gene, while the nodHPQ genes control the synthesis of a sulphated residue positioned at the reducing end. Mutations in either nodQ or nodH result in the production of unsulphated molecules that fail to elicit the responses associated with wild type Nod factor on alfalfa, the normal host legume of S. meliloti. An overview of reciprocal flavonoid and Nod factor signaling in the alfalfa/S. meliloti symbiosis is presented in Fig. 3.

LEGUME ROOT RESPONSES TO RHIZOBIAL NOD FACTORS

Nod factors are essential signals for rhizobial entry into legume roots, through infection threads in root hairs, and for the development of root nodules. Rhizobial mutant strains that have lost the ability to produce Nod factor (for example, by deletion of common nod genes) cannot nodulate their normal host plant, but this property is restored in the presence of purified Nod factor isolated from the parent strain with its full complement of nod
genes. Application of femtomolar concentrations of purified Nod factor to the roots of a host legume elicits several responses that can be detected by biochemical or microscopical analysis: distortion of root hairs accompanied by membrane depolarization and deformation, calcium ion influx and chloride and potassium ion efflux, preinfection thread formation in curled root hairs, and localized cortical cell division at the sites of root nodule primordia. Gene expression studies have shown that Nod factors, even in the absence of their producing rhizobia, can induce some of the plant genes (nodulins) that are involved in the preinfection, infection, nodule

![Diagram](image.png)

![Diagram](image.png)

**Fig. 3** Overview of reciprocal flavonoid and Nod factor signaling in the alfalfa/Sinorhizobium meliloti symbiosis. Flavonoids released from the plant’s roots (1) are received by the constitutively expressed NodD proteins of the bacterium (2). The resulting NodD/flavonoid complex activates transcription of common (3) and host-specific (4) *nod* genes whose enzymes act collectively to synthesize a chitooligosaccharide Nod factor (5) that is transmitted back to the plant root (6). (From Zance, C.P. Root-bacteria interactions: symbiotic N₂ fixation. In *Plant Roots, the Hidden Half*; Waisel, Y., Eshel, A., Kafkafi, U., Eds.; Marcel Dekker, Inc.: New York, 2002; 839–867.)
development, and nodule function stages of symbiotic interaction. Auxin flow in roots at the earliest stages of nodule formation is perturbed by Nod factors, in conjunction with certain endogenous root flavonoids acting as auxin transport inhibitors. Nod factors also control the number of nodules formed on a root system by inducing an autoregulation signal in the host plant. The nature of signal transduction pathways leading from the perception of Nod factors to symbiosis-related gene activation is currently the subject of intensive research. While a breakthrough was recently achieved with the discovery of a receptor kinase gene in *Lotus* and *Medicago* that is required for early signal transduction subsequent to Nod factor perception, the identity of the direct receptor for the Nod factor itself is yet to be established. Interestingly, this receptor kinase is essential for the formation of both rhizobial and AM symbioses with legumes, and it also shares structural features (leucine-rich-repeats) with animal proteins that function in the innate immune system.

While flavonoids and Nod factors are undoubtedly of prime significance as signal molecules in symbiotic development, they are not the only determinants of early recognition between host plant and bacterium. In addition to the chitooligosaccharide Nod factors, rhizobia produce an array of compounds with recognition functions, including extracellular polysaccharides, lipopolysaccharides, K-antigens, and cyclic glucans. In the legume partner carbohydrate-binding proteins on root surfaces, the lectins, appear to mediate host specificity through selective interactions with Nod factors and/or rhizobial extracellular polysaccharides but despite almost 30 years of research on this facet of symbiosis, the details of lectin function remain unresolved.

**CROSSTALK IN MYCORRHIZAL SYMBIOSES**

It is widely recognised that partially overlapping genetic programmes characterise the development of AM and rhizobial symbioses with terrestrial plants; the latter are thought to have recruited genes from the former during their (more recent) evolution, and the previously cited receptor kinase gene in *Lotus* and *Medicago* is one example. Such shared features notwithstanding, little is known about the mechanisms of reciprocal signaling and perception/response in AM symbioses. The obligate biotrophy of AM fungi, which does not allow them to be cultured in the absence of a plant host, and the small quantities of fungal tissue even in highly colonized roots (c. 1% of extracted mRNA is fungal), present obstacles to research into these systems.

AM fungal spore germination, as well as subsequent hyphal growth and branching, are stimulated by root exudates from host plants and CO₂ may act as a volatile signal from the host to direct hyphal growth toward the root surface. Flavonoids are candidates for primary signals from plant root to fungus, mainly on the grounds that they enhance spore germination, but there is no evidence to indicate that they are obligatory compounds or that their mode of action is in any way similar to the one they exhibit in legume-rhizobia symbioses. Contact between fungal hyphae and root epidermal cells is required for the formation of appressoria (fungal structures formed on adhesion to the root surface in advance of host cell penetration) and the plant signal for this stage of infection, though not yet defined, is probably not found in root exudates. The identity of signal molecules from AM fungus to host plant (the equivalent of rhizobial Nod factors) is also unknown, but chitinaceous fragments from fungal cell walls may serve such a purpose. Some pathogen response proteins have been detected in plant roots during the early stages of AM colonization, but the sustained defense response associated with a pathogen attack is either not elicited or is suppressed, as is also the case in legume-rhizobia interactions. Symbiosis-specific gene expression has been detected in both partners and some legume early nodulin genes (e.g., *ENOD2*, *ENOD11*, and *ENOD40* in *Medicago*) are expressed during both rhizobial and AM fungal infections.

As with AM symbioses, the nature of interactive signaling processes in ectomycorrhizae is currently unknown or, at most, ill-defined. Rutin (a flavonoid) and zeatin (a cytokinin) in plant root exudates may stimulate fungal growth in the rhizosphere, while hypaphorine (a fungal alkaloid found in the ectomycorrhizal fungus *Pisolithus*) induces decreased rates and perhaps complete inhibition of root hair elongation in the region of fungal colonization behind the root apex. Interestingly, the host specificity of mycorrhizal fungi appears to be low, while that of rhizobia, as intimated above, is normally high; six genera from the order Glomales form AM symbioses with 80% of angiosperms, whereas, apart from one known exception (*Parasponia*), rhizobial infections are limited to legumes. Among rhizobial species and biovars, particular specificity is further displayed toward individual or small groups of legume genera. Rhizobia with very broad legume host ranges do exist but they may be the exception.

Symbiotic Nitrogen Fixation

Timothy R. McDermott
Montana State University, Bozeman, Montana, U.S.A.

INTRODUCTION

The legume–Rhizobium association is an example of mutualism: Both the plant and the bacterium benefit from their interaction. Microbes have a long history of being somewhat selfish and non-friendly to plants. Indeed, the initiation of this symbiosis (i.e., infection) has many features that are similar to those that initiate pathogenic relationships. When this symbiosis is viewed from the background of the very large number of pathogenic plant-microbe interactions, it is easy to ask questions about how evolution allowed plants to develop divergent relationships with some microbes. In most instances plants appear to go to a lot of trouble to avoid invasion by microbes, whereas in others (i.e., legumes) they will invest significant resources to closely interact with them. This article provides a very general description of the formation and function of the legume–Rhizobium symbiosis.

DISTRIBUTION, ECOLOGY, AND IMPORTANCE

Many aspects of the symbiosis are described in great detail in recent comprehensive overviews.[1,2] Indeed, these major contributions are often cited in this article as source material to intentionally guide readers to more intensive treatment of any of the topics briefly touched upon in the following.

The literature documents over 3000 legume–rhizobia root–nodule symbioses (Table 1), ranging from relatively simple plants such as clover to larger organisms such as shrubs and trees.[3] The nodules formed on the roots of legumes are often categorized into two different groups based on nodule shape, nodule meristem activity, and type of fixed nitrogen products transported from the nodule to the shoot (Fig. 1). Continuing research into the ecology of this symbiosis has shown that it can be found in virtually any climate, ranging from the arctic to the tropics, having evolved essentially the same basic phenotype. In each case, these organisms partner to build a specialized structure known as a root nodule. The nodule houses the rhizobia bacteria, serving as a protective environment where an exchange of metabolites occurs. The host legume provides the rhizobia with photosynthetic sugars for carbon and energy; in return the rhizobia utilize some of these energy-yielding substrates to support nitrogen fixation via the enzyme nitrogenase. The ammonia thus generated is released to the plant.

The ecological advantage afforded to the plant is easily imagined. By taking the risk of allowing the bacteria to infect its roots, the plant stands to benefit by acquiring a limiting nutrient from a pool that it does not have to share with other plants. This symbiotically acquired nitrogen (N) also serves as an important N input to the local ecosystem. The value of legumes in this regard has long been recognized in agriculture, where about 80% of the biologically fixed N is obtained from this symbiosis.[4] Legumes have been used in crop rotations to reduce N fertilizer inputs into a variety of cropping systems, where on a worldwide basis legumes account for roughly 30% of the world’s dietary protein.[5] This is of greatest proportional importance in Third World countries.

ROOT INFECTION AND NODULE ORGANOGENESIS

The legume–Rhizobium symbiosis is species-specific. Some legumes will only nodulate with specific species of rhizobia, and the rhizobia vary, displaying narrow- to broad-host range nodulation capabilities.[6] Nodule formation involves two separate stages—infestation and nodule organogenesis. Infestation is initiated in the rhizosphere when the bacteria find themselves in close contact with newly emerging root hairs in the rhizosphere. The initial interactions occur as a result of a biochemical dialogue that first involves a class of plant root exudates, known as flavonoids, that act as an inducer of nodulation genes in the rhizobia. The flavonoids bind to key regulatory proteins (e.g., NodD in Sinorhizobium meliloti), which then function together to positively regulate the transcription of numerous genes required for infection. Often the nodulation genes are found clustered in a focused location on the chromosome or on large Sym plasmids.[7] These nodulation genes encode proteins that are involved in the synthesis and secretion of lipo-chito-oligosaccharide Nod factors, and in protein secretion. Both of these activities are essential for numerous different aspects of infection initiation.[8] Secretion and release of Nod factors represent...
that compose the nodule primordia. After the infection thread penetrates a nodule primordia cell, the rhizobia are released from the infection thread in an endocytotic process that involves the encapsulation of the rhizobia cells within host plasma membrane derived from the infected cell.[15] Collectively, the rhizobia bacteria and the host-derived membrane structure are referred to as a symbiosome, to reflect the view that it now behaves somewhat like a plant cell organelle.[16] Initially, a symbiosome typically contains a single (or at most two) rhizobial cell(s), at this stage referred to as bacteroids. It should also be pointed out that the symbiosome membrane serves to maintain separation of the rhizobia bacteria from the host plant, avoiding direct contact between the symbionts. This appears to be a common feature for all plant endosymbionts.[17]

This list is not exhaustive, either in terms of legume genera or with respect to nodulation range of some of the rhizobia listed. Some legumes are referred to by their common names, when well-known and available. (For further examples, the reader can refer to [www.honeybee.helsinki.fi/users/lindstro/Rhizobium/Names.html](http://www.honeybee.helsinki.fi/users/lindstro/Rhizobium/Names.html)).

**NODULE FUNCTION**

**Energy Costs**

Carbon fixed during photosynthesis (i.e., CO₂) is used as a source of energy and reductant for nitrogen fixation, carbon skeletons for assimilation of fixed nitrogen, and for bacteroid and nodule growth and maintenance. For each gram of N₂ fixed, roughly 5–10 grams of carbon are needed.[18] In terms of biochemical currency, the nitrogenase enzyme requires at least 16 ATP to reduce one mole of N₂ to 2 moles of NH₃. Part of the high cost of biological nitrogen fixation is due to the production of H₂ that results from the reduction of two protons concomitantly with the reduction of N₂.[19] Some rhizobia have hydrogenase enzymes that could recapture some of the evolved H₂ and thus theoretically reduce
total energy costs; however, experimental demonstration of the latter has been variable and inconsistent.\textsuperscript{[20]}

The symbiosome membrane serves a critical role in controlling metabolite traffic between the symbionts. The bacteroids are completely dependent on the symbiosome membrane for supply and flux of carbon substrates, as well as for removal of fixed nitrogen and bacteroid waste metabolites. The symbiosome membrane contains metabolite-specific transporters that are functionally linked with the biochemical activities of the bacteroids. For example, even though glucose and fructose are abundant in the nodule cytosol,\textsuperscript{[21]} the symbiosome membrane selectively transports organic acids such as malate and succinate,\textsuperscript{[22]} which are metabolites that the bacteroids are well prepared to utilize.\textsuperscript{[20]} On the other hand, in most cases the symbiosome membrane transports the aforementioned hexoses relatively poorly. Likely not coincidentally, the biochemical pathways required to catabolize hexoses are found at low levels in bacteroids of most species of rhizobia.\textsuperscript{[20]}

**Oxygen Paradox**

The role of oxygen in the symbiosis is somewhat of an enigma. The exquisite \(O_2\) sensitivity of the bacterial nitrogenase enzyme is well known and fairly well understood in terms of enzyme function and genetic regulation. However, bacteroids require oxygen as a respiratory electron acceptor for the generation of the large amounts of ATP (i.e., oxidative phosphorylation) required for nitrogen fixation. The problem is solved by control mechanisms that keep oxygen at low levels, yet maintain a steady flow of oxygen to the bacteroids. The outer layers of nodule cells restrict oxygen flux into the nodule by providing a gas diffusion resistance barrier that, when combined with the oxygen consumption of the bacteroids and the plant mitochondria, results in microaerobic conditions.\textsuperscript{[23]} Leghemoglobin is an oxygen-carrying protein in the nodule, composing approximately 20% of the total soluble protein.\textsuperscript{[24]} Its function is similar to that of hemoglobin in blood, serving to transport oxygen throughout the nodule cytoplasm, releasing it as bacteroid and mitochondria respiratory demand requires. Leghemoglobin facilitates increased oxygen flow to the bacteroids and plant mitochondria, without increasing the amount of free oxygen.

**Assimilation of Fixed \(N\) and Transport to Shoot**

Experimental evidence suggests that the ammonium fixed by the bacteroid is released from the bacteroid and exported from the symbiosome,\textsuperscript{[25]} where it is then assimilated by the host into carbon skeletons.\textsuperscript{[5]} However, recent work with soybean suggests that alanine may also serve as a shuttle metabolite that transfers fixed nitrogen from the soybean bacteroid to its host.\textsuperscript{[26]} The ammonia that is released from the symbiosome is immediately incorporated into the amino acids glutamine and glutamate via the host plant enzymes glutamine synthetase (cytoplasm) and glutamate synthase (plastids), respectively.\textsuperscript{[27,28]} In temperate legumes (e.g., pea or alfalfa), the ammonia is transferred to the shoot primarily as the amide asparagine. In tropical legumes (e.g., soybean and bean), the ammonia is incorporated into ureides (allantoin and allantoic acid) and then transported via the xylem to the shoots.\textsuperscript{[27,28]}

Symbiotic Nitrogen Fixation: Plant Nutrition

Timothy R. McDermott
Montana State University, Bozeman, Montana, U.S.A.

INTRODUCTION

Symbiotic nitrogen fixation is one of the most fascinating aspects to legumes. This article briefly describes the mutualistic relationship between rhizobia bacteria and host legume plants and the mechanisms that enable plants such as peas and beans to satisfy their nitrogen requirements through this plant-bacteria association. The article explains what is known about the main nutritional requirements for this relationship aside from nitrogen as well as the basic methods for these assessments. Finally, it very briefly reviews the literature on the implications of specific nutrient deficiencies.

THE RHIZOBIUM-LEGUME SYMBIOSIS: THE ESSENTIALS

The Rhizobium-legume symbiosis forms as a result of a cooperative effort of the rhizobia bacteria and their respective host legume. Beginning with an intricate biochemical dialogue that initiates infection, the bacteria and plant together construct a specialized organ known as the legume root nodule. This symbiosis is viewed to be based on a mutualistic exchange of carbon for nitrogen. The plant utilizes solar energy to fix and reduce CO₂ into carbohydrates, which are subsequently transferred from the leaves to the roots and root nodules. Inside the nodule, these photosynthetic sugars (primarily sucrose) are partially metabolized to organic acids (e.g., malate and succinate), which is the primary form of carbon provided to the bacteroids. The bacteroids utilize these organic acids as an energy source for their nitrogen fixation activity that generates ammonia, which is then released to the plant. The advantage for the legume plant acquiring nitrogen from its symbiosis with the rhizobia bacteria is very clear; nitrogen is most often the limiting nutrient in nonagricultural environments, and thus the plant can gain a competitive advantage in that it does not have to compete for a limited nitrogen pool. For some legumes, the nitrogen acquired from symbiosis can account for almost all of the plant’s nitrogen needs. However, many legumes still rely on soil nitrogen (NH₄⁺ or NO₃⁻) to fill the balance.¹

ASSESSMENT OF MINERAL NUTRIENT NEEDS FOR THE SYMBIOSIS

Three basic approaches for investigating specific roles of individual nutrients in symbiotic nitrogen fixation are typically used and have been discussed previously²,³ (Table 1). Examination of nutrient influences might involve assessing interaction effects with inorganic nitrogen: If a particular element corrects an N deficiency, then a reasonable conclusion is that it impacts, directly or indirectly, on the nitrogen fixation process. Another approach is to examine whether correcting a nutrient deficiency improves nitrogen content in the shoot. Finally, effects of a specific nutrient can be viewed from the perspective of its effect on nodule formation and/or levels of nitrogen fixation as directly measured by acetylene reduction, H₂ evolution, or ¹⁵N isotope dilution.

There are several phases of nodule formation and several aspects of nodule function where a nutrient deficiency can be manifested, and any or all can place a limit on the functioning of this symbiosis. Nutrient shortfalls that directly influence the soil or rhizosphere populations of the rhizobia can in turn impact infection and total nodulation and, thus, potential nitrogen acquired from symbiosis. Some nutrients have been identified to have specific roles at discrete steps in the infection process and nodule formation; furthermore, bacteroid and nodule function may also have unique nutritional requirements. It is not always easy to sort out effects of nutrient limitation on nitrogen fixation per se versus an impact on general host plant growth and well-being that can have ripple effects on nodule function. A legume plant that is metabolically crippled due to a severe nutrient limitation (e.g., S, P, or K) will not be the optimum symbiotic partner. Such an indirect effect is in contrast to the situation where a critical nodule function such as maintenance of optimum oxygen transport functions by leghemoglobin or nitrogen fixation by nitrogenase are specifically dependent upon iron availability.

NUTRIENT REQUIREMENTS FOR OPTIMAL FUNCTION

Nutrient requirements of this symbiosis include host plant requirements as well as the nutrients required for nodule
biomass synthesis, including bacteroid nutritional requirements. Further, nodule tissue may have specialized requirements or perhaps nonspecific sink activity that may influence overall functioning and health of the legume host plant. The requirements of several nutrient elements have been investigated, and while exact mechanisms may not always be completely understood, roles for some have been identified. Macronutrients such as Ca, P, S, and K and micronutrients such as Fe, B, Co, Cu, Mo, Ni, Se, and Zn have been recognized to have specific minimum functions in certain stages of nodule formation and/or function.[2] The roles of macronutrient and micronutrient elements in overall plant metabolism are discussed throughout this article, and specific roles of micronutrients in symbiotic nitrogen fixation are discussed by Dalton in the preceding entry. This entry provides a synopsis of Ca, P, S, and K involvement in the Rhizobium-legume symbiosis. The role of oxygen is discussed in the preceding entry in this article.

CALCIUM

Early studies showed that Ca deficiency can negatively impact nodule formation on numerous legumes [reviewed in Ref. 2]. Many rhizobia grow well at low Ca concentrations (e.g., 15–30 μM)[2] although growth of Sinorhizobium meliloti (alfalfa symbiont) appears especially sensitive to low Ca, and Ca–P interactions further complicate Ca bioavailability.[4] Reduced rhizobia populations might be expected in soils that are deficient in Ca or when the prevailing soil chemistry reduces Ca solubility. Reduced rhizosphere populations could potentially translate into reduced levels of infection. Specific roles for Ca during infection and nodule formation have also been demonstrated. A Ca-dependent adhesin is implicated for attachment of Rhizobium leguminosarum biovar viciae to pea root hairs.[5] For clover rhizobia, Ca is also required for nod gene expression[6] and in Nod factor-based signaling between plant and bacteria in the rhizosphere.[7] Nod factors are also involved in altering Ca gradients and behavior in the tips of infectible root hair cells, resulting in a Ca spiking phenomenon.[8] In alfalfa, the Nod factor brings about oscillations of free Ca in the cytoplasm and is not observed in an alfalfa nodulation mutant.[8]

PHOSPHORUS

In contrast to the other nutrients discussed here, problems of soil P fertility are widespread. Sanchez and Euharal[9] have estimated that crop production on approximately 33% of the world’s arable land is limited by P, with P bioavailability in soil being highly sensitive to the prevailing chemistry. Examples of chronic P fertility problems can be found in the highly weathered soils in the tropics, where acidic pH and high levels of aluminum place significant constraints on P solubility.

Virtually every aspect of the Rhizobium-legume association is affected by P bioavailability. In various legumes, P deficiency has been shown to result in reduced nodulation and nitrogen fixation and lower plant N content and dry matter production. The exact mechanism(s) by which P is involved in these responses is not well understood. The uncertainty in part derives from the likelihood that different legumes have varying P requirements for optimum function, as well as the shear ubiquity of cellular processes that involve or require P. It also stems from our lack of exact understanding of how P deficiency is manifested in this symbiosis, i.e., in nodule-specific activities or as general plant-wide metabolic perturbations that have ripple effects on nitrogen fixation.[10]

As discussed above for Ca, P deficiency could potentially influence rhizosphere populations of rhizobia because different rhizobia respond variably to low P and have different P requirements for growth.[11] Infection experiments show that nodulation efficiency by Bradyrhizobium japonicum (symbiont for soybean) is reduced when cultures are P-stressed prior to inoculation onto soybean roots.[12] Further, P stress negatively influences Nod factor production and excretion by clover rhizobia.[13] Also, extracellular polysaccharide production, which is essential for nodulation by some rhizobia, is also directly controlled by the rhizobial Pho regulon (genetic regulatory system that controls gene expression in response to environmental P levels).[11]

Limiting P will of course diminish overall plant growth. A general consequence of reduced shoot growth could be reduced photosynthesis, which could negatively impact on total photosynthates available for translocation to the nodules. However, there are studies that suggest such a generalized effect is not applicable to all symbioses.[10] Soybean P status is positively correlated with

(Based on Ref. 2.)
nodule-specific nitrogenase activity (total nitrogen fixation/nodule weight) and with nodule ATP content.\textsuperscript{[14]} A still more specific example of how P limitation affects symbiosis involves O$_2$ flux into the nodule. Nodules on P-limited soybeans and alfalfa appear to have increased oxygen permeability.\textsuperscript{[15,16]} Part of this change in O$_2$ flux may be due to decreased nodule size (increased surface-to-volume ratio) that is common with P-limited plants. However, Drevon and Hartwig\textsuperscript{[16]} suggested that this would not account for all of the increase, and other possibilities might include the activation of alternative (i.e., energy wasteful) respiratory pathways that would have the effect of increasing the amount of O$_2$ consumed. Conversely, however, increased nodule O$_2$ uptake could perhaps account for experimental observations showing increases in specific nodule activity in clover\textsuperscript{[17]} under low P growth conditions. The differences in nodule-specific nitrogenase activity between soybean and that of clover is but one example of how the different symbioses respond differently to a nutrient limitation.

**POTASSIUM**

The importance of K in the symbiosis can be inferred at least at a general level because of its roles in water uptake, enzyme activity, and translocation of photosynthates within the plant. A symbiosis-specific function of K has, however, been observed with \textit{Vicia faba} and \textit{Phaseolus vulgaris}, where low levels (0.1 mM) of K in the nutrient solution eliminated nodulation.\textsuperscript{[18]} It is also important to note that in this case and others\textsuperscript{[19]} a supraoptimal K condition was demonstrated in that increasing levels of K increased nodulation without increasing total plant N acquired from symbiotic nitrogen fixation. Other symbiosis-specific functions of K were identified in in vitro studies of \textit{Bradyrhizobium} sp (cowpea) that demonstrated that K is necessary for induction of nitrogenase and heme synthesis,\textsuperscript{[20]} two activities that are of central importance to bacteroid function during symbiosis.

**SULFUR**

Soil S deficiency can have profound effects on this symbiosis. For \textit{Sinorhizobium} and some species of \textit{Rhizobium}, sulfated functional groups are important host-specificity components of Nod factors that are required for nodulation\textsuperscript{[21]} and a significant amount of S is also required for synthesis of the nitrogenase protein.\textsuperscript{[22]} Furthermore, experiments with field-grown subterranean clover\textsuperscript{[23]} have shown that both plant dry matter production and symbiotically derived N are very sensitive to severe S deficiency; incremental increases of applied S ranging from 0 to 8 g·m$^{-2}$ soil resulted in tripling of dry matter productivity and nearly a fourfold increase in N derived from symbiosis. Other experiments have shown variable S responses by different legumes. After S addition to S-limited plants, total plant dry matter increases for \textit{Vicia faba}, \textit{Trifolium pratense}, and \textit{Pisum sativum} were roughly twice that of \textit{Medicago sativa}. For each of these legumes, the proportion of nitrogen acquired from symbiosis appeared to change little in response to the added S, i.e., host plant S requirements were more easily demonstrated than any effect on nodule function.\textsuperscript{[24]}

**CONCLUSION**

Some of the variability in plant and symbiosis response to nutrient deficiency observed in the literature may derive from inherent differences between legume species (and/or cultivars of the same species) for the various nutrients. Indeed, additional in-depth studies with different legumes may ultimately demonstrate that such variability among legumes and symbioses may prohibit convenient nutrient effect modeling. Separating host or host nodule nutritional requirements from those of the bacteroids is not always easy, and indeed understanding source-sink relations in this highly specialized plant organ represents a major challenge to plant biologists. Nutrient flow in and out of the nodule and between bacteroid and host remains poorly understood. It will be important for future studies to dissect the potentially very different needs of bacteroids versus host to better understand the exact role of the various nutrient elements. The roles and specific functions of nutrients will likely vary between symbionts and between symbioses.

Symbiotic Nitrogen Fixation: Special Roles of Micronutrients

David A. Dalton
Reed College, Portland, Oregon, U.S.A.

INTRODUCTION

Nitrogen-fixing plants have special requirements for mineral nutrients beyond those of other plants. The most important nitrogen-fixing plants in terms of agriculture are found in the symbiosis between plants of the legume family (Fabaceae) and bacteria of the genus Rhizobium (or related genera such as Bradyrhizobium and Sinorhizobium, collectively referred to hereafter as rhizobia). Additionally, there are 24 genera of nitrogen-fixing actinorhizal plants that consist of symbioses between various woody plants in 8 families and bacteria of the genus Frankia. No crop plants are actinorhizal, but the alder–Frankia symbiosis is important in forestry. Other actinorhizal plants have significant ecological roles, particularly in enhancing the nutrient status of soil. The complexity of these symbiotic associations results in trace element requirements that are different from those of the individual organisms that participate in the symbiosis. Nitrogen-fixing plants have a unique requirement for cobalt and selenium and an elevated requirement for molybdenum, iron, and nickel, compared to plants that do not fix nitrogen.

COBALT

Cobalt (Co) is essential for all N₂-fixing plant symbioses. This requirement arises from the needs of the endophyte (rhizobia or Frankia) rather than those of the host plant per se. Co plays a major role in symbiotic endophytes as a constituent of vitamin B₁₂ (cyanocobalamin). Plants do not contain vitamin B₁₂. Coenzyme B₁₂ is essential for three types of biochemical reactions: 1) intramolecular rearrangements (e.g., the conversion of L-methylmalonyl CoA into succinyl CoA), 2) methylations (e.g., the synthesis of methionine by methylation of homocysteine), and 3) reduction of ribonucleotides to deoxyribonucleotides. Co does not participate directly in the process of nitrogen fixation.

The requirement of nitrogen-fixing plants for Co was established in 1961 (Fig. 1) [1] using ultrapure nutrient solutions. Symptoms of Co deficiency match those caused by deficiency of nitrogen (e.g., stunted growth, yellowing of tissues) since the symbiotic bacteria are unable to provide the host plant with nitrogen. Because the amounts of Co required are so small, such deficiencies can be demonstrated only by meticulous exclusion of contaminants. Co deficiencies in the field are rare but have occasionally been observed. In some exceptional cases, dramatic increases in yield can result from addition of supplemental Co to crops. [2]

SELENIUM

The requirements of nitrogen-fixing plants for selenium (Se) are less straightforward than is the case for Co. Se is an essential component of hydrogenase, a bacterial enzyme that reclaims energy lost as hydrogen gas, which is produced as a by-product of nitrogenase activity. [3] Although hydrogenase is clearly beneficial to nitrogen-fixing plants, this enzyme is not an absolute requirement. Some rhizobia lack hydrogenase and the plants containing such rhizobia have a reduced yield. [4] Therefore, the selective use of strains of rhizobia that contain hydrogenase is of practical concern in agriculture. The genes for hydrogenase have recently been introduced into rhizobia that lack them, and such efforts may eventually reach applications in the field. [5]

MOLYBDENUM

The role of molybdenum (Mo) in nitrogen fixation by legumes has been recognized since 1950. [6] Mo is a constituent of the molybdenum–iron cofactor (FeMoCo) that is required for nitrogenase activity (Fig. 2). [7] Mo is also essential for the activity of xanthine dehydrogenase, an enzyme that plays an essential role in the synthesis of ureides (nitrogen transport compounds) in some legumes such as soybean, cowpea, and Phaseolus beans. Higher plants and other organisms that utilize nitrates also need Mo for activity of nitrate reductase.

Legumes are particularly susceptible to Mo deficiency (Fig. 3). Symptoms of Mo deficiency have been described
from many parts of the world and are especially common on acidic soils. The application of lime induces changes in soil chemistry that may relieve Mo deficiencies. In some other cases, the response to fertilization with small amounts of Mo can be spectacular.

**IRON**

Nitrogen-fixing plants have an increased requirement for iron (Fe) related to several key proteins involved closely with nitrogen fixation. Fe is a constituent of both of the two components of nitrogenase: dinitrogenase reductase, also called the Fe protein, and dinitrogenase, also called the MoFe protein (Fig. 2). Fe is also a component of ferredoxin, the proximal electron donor to the nitrogenase complex, and of leghemoglobin, a heme (Fe porphyrin) protein that plays a critical role in binding and delivering oxygen for respiration in such a way that nitrogenase is not inactivated. Leghemoglobin may account for up to 50% of the total soluble protein in legume nodules and is responsible for the dark red appearance of nodule interiors that indicates healthy, active nodules. Further indication of the key importance of Fe in nodules is the fact that rhizobia contain siderophores to facilitate the uptake of Fe and that nodules contain phytoferritin to store Fe. This storage is critical; although nodules contain large amounts of Fe, the concentration of free (catalytically active) Fe must be kept low because of its ability to promote the formation of damaging forms of activated oxygen such as superoxide and hydroxyl radicals.

**NICKEL**

Nickel (Ni) has a dual role in the metabolism of nitrogen-fixing plants. Ni is needed for organisms that utilize urea as a nitrogen source and break down urea in their metabolic processes. The breakdown of urea is catalyzed by urease, a Ni-containing enzyme. Urease is widespread in legume leaves and seeds as well as in bacteroids and free-living rhizobia.[8] The precise metabolic role of urea and urease in regard to nitrogen fixation is not clear, but it is likely that urease is involved in the processing of nitrogenous compounds transported from nodules to leaves. Soybeans and cowpeas grown in purified nutrient solutions in symbiosis with rhizobia develop necrotic leaf tips when the Ni supply is inadequate.[9] This necrosis is due to high concentrations of urea that accumulate due to the lack of urease activity. Soybeans grown with fixed nitrogen also have a Ni requirement, but the magnitude of this requirement appears to be less.

Nitrogen-fixing symbioses also require Ni as a component of hydrogenase—an enzyme that participates in the conservation of energy as discussed earlier with respect to Se. Ni deficiency in soybean plants results in a significant decrease in hydrogenase activity in nodule

bacteroids. The amount of Ni required by plants is extremely low, and there are no reports of Ni deficiency in the field. However, some soils contain inadequate Ni for the optimum activity of urease in the indigenous soil microorganisms. Furthermore, inoculated soybean plants grown on low-nickel soil exhibited increased activities of urease in leaves and hydrogenase in nodule bacteroids when nickel was provided.\[8\]

OTHER ELEMENTS

Rhizobia also require other micronutrients such as manganese, copper, and zinc\[10\] but these elements do not play a direct role in nitrogen fixation. Boron is not required by rhizobia, but is necessary for the formation of legume nodules. Also, it is noteworthy that although some nitrogen-fixing bacteria (e.g., Azotobacter) have “alternative” nitrogenases that utilize vanadium instead of Mo, there is no evidence for the presence of such alternative nitrogenases in symbiotic bacteria such as rhizobia or Frankia.

Tobamoviral Vectors: Developing a Production System for Pharmaceuticals in Transfected Plants

Jennifer Lee Busto
Monto H. Kumagai
University of Hawaii at Manoa, Honolulu, Hawaii, U.S.A.

INTRODUCTION

Transgenic crops have played a predominant role in the production of pharmaceuticals and other valuable biological molecules. A more efficient strategy has involved inoculating nontransgenic plants with virus-based vectors that carry foreign genes. With the development of infectious cDNA clones, single-stranded RNA plant viruses have become key players in gene function discovery, metabolic engineering, and biomanufacturing. Viral expression vectors provide epigenetic expression of foreign sequences throughout infected plants, leading to gain- or loss-of-function phenotypes due to overexpression or cytoplasmic inhibition of gene expression.

Plant viruses are powerful transfection tools in molecular farming, producing pure, properly folded and glycosylated proteins in plants faster and more economically than other expression systems. They are a highly desirable alternative to transgenic systems that require protracted periods to transform and regenerate whole plants, and that have variation in the expression levels of heterologous proteins. In transgenic systems, once a particular construct is inserted into the plant genome, it may take several crosses to establish a stable line in an elite cultivar. In contrast, plant viral vectors employed in the large-scale production of therapeutic drugs in greenhouse and field-grown crops directly yield high levels of foreign protein, due to the rapid rate of viral replication. In plants transfected with a recombinant tobamovirus, alpha-trichosanthin, a potential anti-AIDS drug, accumulated to approximately 2% of total soluble protein.

Therapeutic compounds stably produced in transfected plants are numerous, and include antiviral drugs such as human interferon-alpha 2 as well as vaccines, proteins, and secondary metabolites. Plant-derived anticancer vaccines have been produced for treatment of human papillomavirus-induced cancer by expressing recombinant E7 fusion oncoproteins in *Nicotiana benthamiana*. The HIV p24 nucleocapsid protein, used as an antigen in the development of HIV vaccines, has been produced in plant protoplasts using tomato bushy stunt virus (TBSV) vector. For viruses that cannot be grown in tissue culture, such as hepatitis C (HCV), tobamoviral vectors are under development to produce a plant-derived vaccine. Recombinant proteins for use in diagnostics have also been expressed in plants. Full-length recombinant monoclonal antibodies (rAbs) directed against a colon cancer antigen and recombinant allergens have been expressed in *N. benthamiana* leaves, using a tobamoviral vector. The binding of IgE from sera of birch pollen- and latex-allergic patients suggests that the plant-produced allergens are properly folded.

TOBACCO MOSAIC VIRUS VECTORS

Several virus groups have been under investigation for design as recombinant plant virus vectors, including geminiviruses, potyviruses, potexviruses, comoviruses, tombusviruses, tobraviruses, alfamoviruses, and hordeiviruses. Members of the tobamovirus group are the most widely studied. The autonomously replicating RNA viral vectors based on the tobacco mosaic virus (TMV) genome have been particularly successful as research and commercial tools.

TMV possesses a positive-sense, single-stranded genome of 6396 nucleotides that encodes replicate enzymes, and movement and coat proteins. Viral genes are expressed through the production of both genomic and subgenomic RNA. Essentially designed as cDNA plasmids, TMV vectors are modified to contain a foreign gene sequence. Originally, vectors were constructed with the gene of interest replacing the capsid protein, until it was recognized that these viral vectors do not move efficiently. Presently, TMV vectors are hybrid versions of several different strains of tobamoviruses that include all essential viral genes, a bacterial origin of replication (ori), and an antibiotic resistance marker. Dual heterologous subgenomic promoters from related tobamoviruses have enhanced stability, while an internal ribosome entry site sequence (IRES) has been incorporated into the design to enable expression of multiple proteins.

The transfection process involves mechanically inoculating recombinant in vitro RNA transcripts from viral cDNA clones onto plants. Recombinant virions are...
assembled in the plant and move systemically by associating with plasmodesmata and intercellular cytoplasmic channels, producing foreign protein as they travel. One to two weeks after inoculation, recombinant proteins can be isolated from transfected plants. Interstitial fluid containing the desired product can be quickly separated from other cellular proteins by vacuum infiltration and gentle centrifugation. For large agronomic applications, virions can be purified from transfected plants and used for subsequent inoculations using high-pressure sprayers in the field.

**Viral Vector Design Construct**

For vaccine production, TMV vectors have been developed as coat protein (CP) fusions with the viral coat providing a flexible framework for the recombinant protein. TMV CP fusions include human immunodeficiency virus type I (HIV-I) peptide, influenza virus hemagglutinin epitope, malaria parasite peptide, and hepatitis C virus epitope. A key technical advance in design has enabled TMV vectors to produce free proteins that are not fused to the coat protein. Instead, genes encoding bioactive compounds are fused to signal peptide sequences that cause the translated protein to be processed via the endoplasmic reticulum and Golgi complex, and to be targeted for cellular secretion. It is recognized that the faithful and efficient expression of such heterologous proteins is influenced by the choice of the signal peptide.

One of the most highly efficient TMV vector constructs fuses the gene of interest to a sequence encoding a rice α-amylase signal peptide adjacent to a 5′ untranslated leader. Viral vectors containing the rice α-amylase signal peptide ORF have been used to express a wide variety of heterologous proteins including mammalian peptides, blood products, glycoproteins, and cytokines. TMV vectors that incorporate this signal peptide have been used successfully to secrete single-chain variable-fragment (Fv) antibodies for the treatment of non-Hodgkin’s lymphoma (NHL). Currently in Phase II/III clinical trials, these highly customized patient-specific vaccines act as antitumor agents.

The rice α-amylase 5′ untranslated leader sequence may help to enhance translation of the heterologous protein. The highly expressed viral coat subgenomic RNA has a 5′ cap (m7GpppN) and terminates with a tRNA-like structure instead of a poly (A) tail. The 3′ untranslated region (UTR) has two domains, which contain five RNA pseudoknots. It is possible that interactions between the 34-base pair 5′ leader of α-amylase and the 3′ UTR may cause a synergistic regulation of translation in transfected plants. Significantly, the rice α-amylase signal peptide has been recognized and processed in other transformed organisms, including *Escherichia coli*, *Saccharomyces cerevisiae*, and *Yarrowia lipolytica*, as well as transgenic rice cell suspensions. Subtle differences in the size, source, and sequence of the α-amylase signal peptide can greatly affect the secretion process.

Striving for higher protein yields, researchers are collaborating to develop improvements in vector design for increased production. It is recognized that inclusion of

![Fig. 1](Image) Overexpression of phytoene synthase (crtB) in leaves of *Nicotiana benthamiana* produces an orange phenotype. (Photo courtesy of Tony Novelozo—Axiom, Davis.) (View this art in color at www.dekker.com.)
foreign genes into TMV vectors reduces efficiencies of replication and movement compared to the wild type. These studies are aimed at improving the ability of these vectors to move and to replicate through gene shuffling of the 30K movement gene.\[^9\] Visible markers for heterologous gene expression in plants are also under development. Tobacco mosaic viral (TMV) vectors have been engineered to overexpress an enzyme involved in carotenoid biosynthesis in \textit{N. benthamiana} and other solanaceous plants.\[^14\] As the viral genome is translated, the encoded enzyme, phytoene synthase (\textit{psy}), is targeted to the chloroplast, causing an accumulation of phytoene, a colorless compound. However, transfected plants show a characteristic orange phenotype in the leaves and flower sepal, as early as four days post-inoculation (Fig. 1). If fused to a heterologous sequence in a recombinant vector, \textit{psy} may serve as a useful marker for gene expression, particularly in field applications.

**Metabolic Engineering**

Although plant viruses that are engineered to produce pharmaceutically relevant proteins have proved to be powerful gene expression tools, they are also valuable tools for use in gene discovery and in the metabolic engineering of existing pathways in plants. The biosynthesis of leaf carotenoids in transfected \textit{N. benthamiana} was altered by forced rerouting of the pathway, resulting in the synthesis of capsanthin, a non-native chromoplast-specific xanthophyll. The ectopic expression of capsanthin–capsorubin synthase (\textit{Ces}) cDNA caused the plant to develop an orange phenotype and accumulate high levels of capsanthin—up to 36\% total carotenoids. By redirecting the existing pathways of plants that produce biologically active compounds, plant virus expression systems can potentially be used to alter or to produce novel enzymes, or cause the accumulation of non-native bioactive compounds.\[^10\]

**CONCLUSION**

Plant RNA viral vectors have become intensively utilized in several different plant species for large-scale production of high-value therapeutic proteins\[^11\]–\[^13\] and secondary metabolites.\[^5\] The United States Food and Drug Administration (FDA) has developed a guidance document on plant-derived biologics and has strengthened field-testing controls for permits on those bioengineered traits that are not intended for commodity uses, such as pharmaceuticals, veterinary biologics, or certain industrial products. The human safety of TMV-based expression systems has been documented; plant viruses are not pathogenic to humans. TMV is only transmitted to other plants through mechanical means; proper cleaning of tools and machinery with bleach contains the virus and TMV-based vectors. In addition, FDA demands for recombinant product purity are rigorous.

To date, at least nine separate field trials using viral-based vector systems for the production of biologics have been conducted in three separate states. Concerns regarding the spread of engineered TMV and the persistence of recombinant viruses have been addressed in these studies, and a recent report indicates that recombinant viruses generally delete the foreign gene, have reduced vigor, and are less competitive and pathogenic than the indigenous TMV.\[^14\] Plant viral vectors are also effective tools in metabolic engineering, as well as gene function discovery.\[^15\] Design modifications will lead to improvement of desirable vector traits so that the potential of plant virus vector gene expression systems is fully realized.\[^2\]

INTRODUCTION

Transformation (or genetic engineering) has provided a powerful tool to introduce and modify traits desirable for crop improvement. Transgenes can now be incorporated into any cultivars across the genetic barriers for many crop species. Genetic transformation can be achieved by several methods (protoplast, biolistic, Agrobacterium tumefaciens, etc.) and a large number of successful crops have now been developed and commercialized. It is now possible to develop crops engineered with genes for built-in plant protection, durable resistance, and nutrition improvement. In the genomics era, gene discovery will accelerate further crop improvement and precision breeding, using high-throughput genetic transformation.

Plant improvement based on genetics has been occurring for years. In traditional breeding, genetic modifications are made by making crosses between related organisms. This depends mostly on reciprocal crossability and selecting for specific desirable traits. With the use of recombinant DNA technology, it is now possible to remove a piece of DNA containing one or more specific desirable genes from any organism and introduce it into another organism. Transformation is the step in the genetic engineering process that involves the incorporation of genes into genomes by means other than fusion of gametes or somatic cells. The incorporation and expression of foreign genes in plants, which is now possible in at least 35 families, was first described in tobacco. The plant transformation approach is being used to produce plants possessing traits unachievable by conventional plant breeding, especially in cases where the gene pool contains no source of the desired trait. Improved transgenic crops have been developed and field-tested in many countries and will have great impact in the developing countries.

Seven transgenic crops—maize, cotton, canola, rapeseed, potato, squash, and papaya—are being produced commercially in 12 countries, including the United States, Argentina, Canada, China, and India. Elite transgenic indica rice has now been evaluated. It showed excellent performance against insect pests and bacterial blight.

Different systems have been developed to integrate foreign DNA into plant cells and to carry out the successive regeneration of transgenic plants, as shown in rice as a model monocot plant. Commonly used methods are based on biological vectors (e.g., Agrobacterium, virus), physical techniques (e.g., particle bombardment), and chemical techniques (e.g., PEG-mediated protoplast transformation). Besides the transformation methods, the basic requirements for the production of transgenic plants are: 1) the availability of target tissues to be transformed that are competent for plant regeneration; and 2) a suitable selection system for regenerating transformed plants with reasonable frequency. An efficient system for selecting only a few transformed cells from among a large number of nontransformed cells, and recovery of plants from single transformed cells is essential.

AGROBACTERIUM-MEDIATED TRANSFORMATION

In nature, the gram-negative soil bacterium Agrobacterium tumefaciens infects wound sites in dicotyledonous plants, causing the formation of crown gall tumors by a multistep gene transfer procedure. Virulent strains of A. tumefaciens and A. rhizogenes possess the ability to transfer a particular DNA segment (T-DNA) of the extra chromosomal tumor-inducing (Ti) plasmid.[1] The T-DNA is surrounded by 24-base-pair (bp) border repeats and contains two types of genes, oncogenic genes and the gene encoding for the synthesis of opines. The oncogenic genes encode for the enzymes involved in the synthesis of auxins and cytokinins, whose expression leads to tumor formation. Outside the T-DNA, a large number of other genes (vir genes) in Ti plasmid are involved in this transfer mechanism. The T-DNA transfer system is determined by vir genes, whereas 24-bp direct repeats act as the recognition signals for the transfer.

Binary Vector System for Agrobacterium-Mediated Transformation

On the basis of the naturally occurring gene transfer mechanism of crown gall formation, the Agrobacterium
A range of improved virulent and binary systems has been developed. The supervirulent wider host-range Agrobacterium strain A281 possesses a transformation efficiency higher than that of other strains because of the presence of the pTiB0542 plasmid. The strain EHA101 also carries the disarmed version of pTiB0542. In the superbinary system, the virB, virC, and virG genes from the virulence region of pTiB0542 are inserted into a small T-DNA-containing plasmid in addition to the disarmed Ti plasmid with its full set of virulence genes.

Agrobacterium-mediated gene transfer into monocotyledonous plants became possible only recently; efficient methodologies have been reported in rice (Table 1).

In Planta Transformation

Successful Agrobacterium-mediated transformation has recently been reported in Arabidopsis, in which the transformation takes place in planta: The transformed tissue is not removed from the plant but left in a natural condition. In the in planta system, panicles at the early flowering stage are usually used as a target tissue. Successful in planta transformation of the legume Medicago truncatula
BIOLISTIC TRANSFORMATION (GENE GUN) SYSTEM

The biolistic (or gene gun) method for transformation involves the direct physical method of delivering nucleic acids into cells. In this system, metallic (gold or tungsten) microparticles are coated with DNA (transgene construct) and fired into target cells, shot with a particle bombardment machine. The particles are accelerated with an electrical discharge or compressed helium gas. Microprojectile bombardment of immature embryos to deliver the DNA into plant cells, and recovery of the whole plants from the transformed cells through selection are becoming almost routine (Fig. 1). Because there is no biological limitation to DNA delivery, genotype-independent transformation may be carried out with this method. Different rice cultivars have been transformed by this system.[5] Bombardment often results in multiple insertions of transgene copies in different loci and extensive rearrangement of the introduced gene, which may in some cases lead to expression instability of the transgene.

MICROINJECTION

In the microinjection method, DNA is injected directly into the nucleus of a cell using an ultrafine needle. The
target cells are usually small structures with only a few cells and high regeneration potential (e.g., microspore-derived and zygotic proembryos). This method is not suitable for a plant system but is used routinely to produce transgenic animals.\(^6\)

**LIPOSOME-MEDIATED TRANSFER**

DNA is encapsulated in liposomes (lipid micels). Liposomes help the DNA to enter through the plasmodesmata or the lipids to impregnate the cell walls, making it easier for DNA to penetrate. This method is not very efficient in transferring DNA to target cells.\(^6\)

**WHISKERS METHOD**

Tiny microscopic needlelike structures with sharp end fibers of silicon carbide (or whiskers) are used in this method of genetic engineering. Embryogenic tissue culture cells, DNA of interest, and whiskers are suspended and shaken together robustly. The collision between the cells and sharp whiskers creates small holes in the cell wall to deliver the desired gene into the nucleus of the cell. This system has been used successfully for maize.

**SELECTION SYSTEM**

A suitable selectable marker gene is a prerequisite in distinguishing transformed cells from nontransformed ones. \(nptII,\) \(hph,\) and \(ppt\) are the most effective genes encoding neomycin phosphotransferase, hygromycin phosphotransferase, and phosphinothricin acetyltransferase, respectively.\(^7\) Recently, the nonantibiotic POSITECH™ selection system has been developed using the \(phosphomannoseisomerase (PMI)\) gene available from Syngenta.\(^8,9\)

**CONCLUSION**

Tremendous improvements in basic transgenic technologies have been made, to the extent that all major crop plants are now transformable and available for improvement with these technologies. Transformation protocols differ from one plant to another and, within species, from one cultivar to another. The optimization of transformation methodologies requires the consideration of several important means, such as the use of suitable explants, a mode of gene delivery, and plant regeneration. Maternal inheritance of foreign genes through chloroplast engineering can be used for those crops in which potential outcrossing is possible. Gene flow or outcrossing is very common in crops such as sunflower and strawberry. This technology is an alternative to overcome concerns regarding nuclear genetic engineering. However, gene flow is a natural phenomenon, and so far has not caused weediness or other negative effect on the environment.

Currently used transformation methods do not allow precise prediction of the position and number of copies of transforming DNA to be integrated into the host-cell genome. The tissue-and development-specific regulation of the gene depends on the choice of the promoter regulating the transcription of the transgene or the transit peptide directing the product to specific organelles. Transgene pyramiding and gene stacking using multiple genes of diverse traits are now possible, and will help in further crop improvement. The \(sd1\) gene principally involved in the green revolution can now be used to shorten plant height (to avoid lodging) and preserve traditional tall varieties. The main effect of genetic transformation lies in developing an improved product—seeds.\(^10,11\)

INTRODUCTION

Transgenic plants or food crops are genetically modified organisms (GMOs), meaning that genes have been introduced or silenced in their genomes using methods other than sexual crossing. These genetic modifications can provide a variety of useful traits, including herbicide resistance, pest resistance, and enhanced vitamin content.

Genetically modified (GM) crops were grown on an estimated 58.7 million hectares (145 million acres) in 2002 by from 5.5 to 6.0 million farmers in 16 countries. It is interesting to note that more than three-quarters of the farmers who grew GM crops could be considered small-scale and resource-poor. The principal GM crops during this period were soybean (36.5 million hectares), corn (12.4 million hectares), cotton (6.8 million hectares), and canola (3.0 million hectares).[1]

Due to recent debates about safety, some countries are requiring disclosure of GM derivatives in foods, creating the need for reliable detection methods.

METHODS FOR DETECTION OF TRANSGENES

Current methods focus on detecting a molecule—DNA, RNA, or other proteins—associated with or derived from the genetic modification of interest.[2] DNA is the preferred target, because it is very stable and can be purified, and billions of copies of a particular strand can be made in just a few hours using the polymerase chain reaction (PCR), producing quantities large enough for easy detection.[3,4] Multiplication of RNA and other proteins is slower and more complicated. There is also a linear correlation between levels of GM derivatives in a sample and the DNA, if the genetically modified DNA comes from cell nuclei. No such correlation exists in the case of proteins or RNA.

To detect GM DNA using PCR, the double-stranded helix of the target DNA is separated and mixed in a solution with short pieces of synthetic, single-strand DNA known as “primers.” The solution contains a cellular enzyme called DNA polymerase, which among other of its natural functions contributes to the repair and replication of DNA. Each primer is “complementary” to one or the other end of the single strands of the target DNA. This means that the sequence of nucleotides (the amino acid building blocks of DNA and RNA) in the primer is such that it will bind to the DNA. The first primer matches the start and the coding section of the DNA to be multiplied, while the second primer matches the end and the noncoding portion of the DNA. The portion of the target strand in between is filled in with nucleotides from the polymerase solution, creating two double-stranded DNA molecules that are perfect copies of the original. By raising and lowering the temperature of the solution, the double strands are newly “unzipped” and the filling-in process begins again, using the complementary strands as templates. For each temperature cycle the number of copies is doubled, resulting in an exponential multiplication of the original DNA sample. After 20 cycles the copy number is approximately 1 million times higher than at the beginning.

One of the most common techniques to estimate the amount and size of DNA or RNA strands in a sample is gel electrophoresis. Prior to this, the DNA may be “digested”—that is, put in solution with enzymes known to cut the DNA at sites where there is a specific sequence of nucleotides, resulting in fragments of particular sizes. A more sophisticated technique involves determination of melting point profiles by means of dyes like SYBR Green I, which emits fluorescent light when it intercalates with double-stranded DNA. When the temperature is increased, the DNA strands begin to separate, reducing the fluorescence in readily measurable amounts. The melting point is more characteristic of a specific DNA sequence than of its size, but complete sequencing—determining the exact order of the nucleotides throughout a DNA or RNA fragment—allows for more specific determination of the origin of the molecule. A fourth alternative is to use short, synthetic molecules called “probes,” which bind to given sites on a DNA or RNA...
strand. If appropriately designed, a probe will be able to discriminate between the correct molecule and almost any other DNA or RNA molecule. Labeling with fluorescence, radioactivity, antibodies, or dyes also facilitates detection of the molecules present.\[5\]

Protein-based detection of GM derivatives relies on the specific binding between a protein and an antibody, a molecule of the type that protects against bacterial and viral infections in the human body. The antibody recognizes a foreign molecule—the “antigen”—and binds to it. The bound complex is detected in a chemical reaction that causes a particular color to appear. This technique is known as the enzyme linked immunosorbent assay (ELISA) and combines the specificity of antibodies with the sensitivity of simple enzyme assays. ELISA can provide an easy and precise measurement of antigen or antibody concentrations.

One of the most useful of the immunoassays is the two-antibody “sandwich” ELISA. It is a fast and accurate way to determine the antigen concentration in unknown samples. It requires two antibodies that bind to different positions on the same antigen. This can be accomplished using either two monoclonal antibodies—ones that attach to single sites—or a batch of affinity-purified polyclonal antibodies. The antibodies for this technique must be developed using purified samples of the target protein, taken either from the GM derivatives themselves or synthesized, if the exact composition of the protein is known.

RNA-based methods rely on specific binding between the RNA molecule and a synthetic RNA or a DNA strand as the primer. The primer nucleotides must again complement those at the starting end of the RNA molecule. Binding results in a double-stranded molecule similar to DNA and, normally, the subsequent conversion of the RNA to a DNA molecule through a process called reverse transcription. Finally the DNA can be multiplied using PCR or transformed into as many as 100 copies of the original RNA molecule and the procedure repeated, using each copy as a template, in a technique called nucleic acid sequence-based amplification (NASBA). The specific primers cannot be developed without knowing the exact composition of the RNA molecule to be detected.\[5\]

**SAMPLING TECHNIQUES**

To date, 72 transgenic varieties have been developed in 17 plant species (Table 1). There is insufficient space here to describe one-by-one all sampling methods to detect GM derivatives in seed; in any case, many methods will likely become obsolete soon, with the rapid development of new transgenic varieties and detection methods. This aside, there are two key problems in seed sampling that must be understood: 1) the limit of detection and 2) sampling error.\[6,7\]

The amount of unreplicated haploid genome (i.e., the 1C value, the amount present in a gamete) in a sample is useful for relating genome copy number to the amount of sample taken. For example, up to 36,697 copies of the haploid *Zea mays* genome (which we will use here as the basis for all examples below) are present in a typical 100 ng DNA analytical sample, given the 1C value of 2.725 picograms. It follows that a single copy of the haploid *Z. mays* genome in a 100 ng DNA sample is present at a level of 0.0027% (wt/wt). Levels of DNA below this threshold cannot be detected reliably in samples of this size.\[4\]

Sampling error occurs in a perfectly homogeneous preparation, even if a large amount (say, 50 μg) of DNA is extracted from a laboratory sample and simple random sampling procedures are adopted. As the amount of DNA extracted from the sample becomes lower, sampling error becomes proportionally larger. Thus, replicate 100 ng DNA samples containing GMO material at a level of 0.1% (wt/wt) would produce GM DNA estimates no better than approximately 30% of the mean value 95% of the time. This is a poor level of accuracy, even if we ignore other types of error inherent to a real analytical system.

With lower levels of DNA, the problem is even more critical. For a laboratory sample containing DNA at a level of 0.01%, the 100 ng analytical sample would vary between 0.0027% and 0.0191% nearly 95% of the time. These calculations obviously refer to a “best possible” result, as they assume a single sampling step and a perfect analytical system.

When undertaking a dilution series, the assumption of simple random sampling may no longer be valid, as the number of copies available becomes strictly finite. Indeed, the number of copies used to prepare subsequent dilutions heavily influences the sampling error associated with the series. Consequently, the preparation of any dilution series must be undertaken in such a way as to minimize this bias; ideally, dilutions should be made from the primary laboratory sample.

The classical solution to the issue of sampling error is to undertake repetitions and/or use appropriately sized analytical samples. We recommend that in the construction of a dilution series—for example, to determine the “limit of detection” of a method, or for the generation of standard curves—the nominal number of GM-derived copies in the weakest dilution of analytical sample should be set to approximately 20, thus providing good statistical probability that all repetitions contain relevant DNA.

This chapter endeavors to explain the methodologies used for the detection of transgenes, transgene products,

INTRODUCTION

It is hoped that transgenic technology will be a solution for feeding the increasing world population. However, as the use of transgenic crops has increased, evidence has accumulated that the expression of a desired transgene may be unstable. To ensure that plants with unstable transgene expression are kept from reaching market, extensive testing is needed, which requires higher production costs. Even this testing is still not a guarantee that an apparently stable trait will remain stable under all environmental conditions. The purpose of this review is to provide the reader with a greater understanding of the molecular events related to how and why gene silencing occurs. Possible strategies for preventing undesirable gene silencing are also discussed, and examples are given of gene silencing used as a tool to understand gene function.

The discovery of gene silencing in plants laid the groundwork for findings that gene silencing is found in all higher eukaryotes. Historically, unstable transgene expression in plants was ascribed to "chromosomal position effects." According to the chromosomal position-effect model, transgenes integrated into regions of the genome containing uncondensed chromatin were more likely to be expressed. Conversely, transgenes integrated into regions of the genome containing condensed chromatin were less likely to be expressed. While extensive evidence for chromosomal position effects exists, homology-dependent gene silencing is now also known to be a major determinant for transgene expression.

POST-TRANSCRIPTIONAL GENE SILENCING (PTGS)

More than a decade ago a fortuitous observation was made when Jorgensen and his colleagues attempted to "overexpress" chalcone synthase (CHS) in petunia, using a transgene sequence that was identical to the sequence of the natural gene. To achieve overexpression of CHS, a viral promoter known to give high levels of gene expression was used, with the expectation that purple flowers would be produced. Instead, the CHS overexpressing transgenic plants produced flowers that showed various patterns of purple and white. When the CHS messenger RNA (mRNA) levels in the white and purple sections were compared, the mRNA levels from white sectors were drastically reduced for both the CHS transgene and the native petunia CHS gene. The result was verified when van der Krol and colleagues tried to overexpress a petunia flavanoid gene. Both groups concluded that a major requirement for gene silencing was sequence homology between the transgene and the native gene.

Nearly three years later, research on plant virus resistance provided additional clues to the gene silencing puzzle. For several years, it was known that a transgenic plant expressing a viral coat protein for a specific virus had a higher frequency of resistance to the virus. Such observations led to speculations that the viral coat protein prevented the uncoating of the infecting virus and thus interfered with viral replication. Experiments by Dougherty and colleagues resulted in an alternative explanation, in which high levels of viral mRNA expressed from a plant transgene resulted in virus resistance. The transcription rates were similar for both virus-infected and uninfected plants, but no transgene viral mRNA accumulated, indicating that resistance was at the post-transcriptional level.

The model proposed by the Dougherty group suggested that an RNA-dependent RNA polymerase (RdRP) produced an antisense RNA that led to the degradation of both the viral RNA and the transgene "viral" RNA. We now know that the type of gene silencing observed over a decade ago in petunias was post-transcriptional gene silencing (PTGS), which also has been shown to be a natural mechanism plants use for virus resistance.

To circumvent plant defense systems, many viruses have suppressor systems that interfere with PTGS. Thus transgenic plants that constitutively express the viral suppressors of silencing have impaired PTGS, which led to ideas that the suppressors could be used for high-level transgene expression. Unfortunately, plants that express the viral suppressors show developmental abnormalities. Such silencing-suppressed plants may be extremely sensitive to viruses under natural growing conditions, because silencing is a defense against viruses.

Recent work has shown that RdRP uses the mRNA template to produce double-stranded RNA (dsRNA), which is then degraded to small RNAs, leading to the initiation of PTGS. Although the production of the
small RNAs was discovered in plants,[7] the same pathway occurs in animal and fungal systems. Mutant and biochemical analyses are now increasing our understanding of the genes and signals involved in PTGS.

TRANSCRIPTIONAL GENE SILENCING (TGS)

TGS and PTGS typically are distinguished by nuclear run-on assays that compare transcription rates with the steady-state mRNA levels. A gene silenced by TGS has undetectable transcription and undetectable mRNA, whereas a gene silenced by PTGS is transcribed but has greatly reduced levels of mRNA. Additionally, TGS can be inherited, whereas PTGS requires reactivation in every generation.

To understand TGS it is useful to have a basic understanding of chromatin structure. Chromatin consists of proteins that bind and package DNA into successive levels of higher-order structures, which we eventually see as eukaryotic chromosomes. The structure of chromatin can control access of the transcriptional machinery to the DNA. If the chromatin is uncondensed, the transcription apparatus has ready access to promoters. Condensed chromatin, on the other hand, prevents access to a promoter.

Initial work on TGS demonstrated that when a transgene integrates near a region of condensed inactive chromatin, the inactive chromatin could spread into the transgene and prevent transcription. Drosophila studies showed that silencing frequently resulted in variegated expression patterns, known as position-effect variegation. Thus, in typical TGS, the promoter is made inaccessible by the condensed chromatin and cannot be transcribed.

PREVENTION OF TRANSCRIPTIONAL GENE SILENCING

A major limitation in the use of transgenes has been unpredictable variation in expression. To reduce the variation caused by TGS, attempts were made to block the spread of condensed chromatin. DNA elements termed matrix attachment regions (MARs) from the chicken lysozyme gene were used to flank a transgene.[8] The results showed that transfected mammalian cell lines had higher levels of transgene expression and lacked chromosomal position effects when MARs were used.

Work from the Allen and Thompson lab tested whether MARs could prevent silencing in plants using the beta-glucuronidase (GUS) reporter transgene, either flanked by yeast MARs or lacking MARs.[9] Comparison of the GUS transgene copy number and expression levels revealed that the GUS expression levels were much higher in tobacco cell lines transformed with MAR-flanked transgenes. However, even in the cell lines transformed with reporter constructs using the flanking MARs, a drastic reduction in transgene expression was seen when the transgene copy number increased above a threshold of approximately 20 copies. Similar results were found when a tobacco MAR was used.

We now know that silencing is possible, when gene copy numbers are above a threshold even in cell lines with MAR-flanked transgenes, and that this silencing is likely due to PTGS. In contrast to lines containing MAR-flanked transgenes, the control cell lines were subject to silencing by both TGS and PTGS. When cell lines expressing a suppressor of PTGS were retransformed with reporter genes flanked by MARs, silencing was drastically reduced. Presumably the flanking MARs prevented TGS and the viral suppressor prevented PTGS. Thus, MARs appear to prevent TGS but not PTGS.[10]

GENE SILENCING AS A TOOL FOR FUNCTIONAL GENOMICS

With genome sequences rapidly being completed for many organisms, attention is being focused on the area of functional genomics. While microarrays provide information on gene expression patterns and possible gene interactions, understanding how a gene impacts phenotype is limited by the lack of tools for producing functional knockout mutants. PTGS (or RNAi) is now providing scientists with a new tool for knocking out specific genes or groups of genes by using dsRNA to induce gene silencing.[11] The resulting phenotypic knockout can then be examined to determine gene function. By combining the use of high-throughput RNAi with microarray analyses, the effect of knocking out a single gene can be determined for an entire array of expressed genes, allowing scientists to determine the impact the gene has on global gene expression. Thus, gene silencing offers a unique tool for understanding how genes are regulated in complex organisms.

Transgenic Plants: Breeding Programs for Sustainable Insect Resistance

Michael B. Cohen
University of Alberta, Edmonton, Alberta, Canada

INTRODUCTION

Genetic engineering of crops with crystal toxin (Cry) genes from *Bacillus thuringiensis* (Bt) has been a revolutionary development in plant breeding for resistance to insect pests.[1] Because Bt toxins are highly effective against several important groups of pests, yet are largely benign to non-target organisms, unprecedented measures have been taken in the United States,[2] Canada,[3] and Australia[4] to delay the evolution of pest adaptation to Bt crops. Resistance management strategies for Bt crops depend on proper deployment of Bt cultivars in farmers’ fields and on the development of cultivars with appropriate toxin genes and toxin titers. This article provides an introduction to the principles of resistance management and recommends steps that genetic engineering programs and government regulatory agencies can take to promote the sustainable use of Bt crops.

THE REFUGE/HIGH DOSE STRATEGY

There is widespread agreement that the refuge/high dose strategy (Fig. 1) is the most promising approach for protecting the long-term effectiveness of transgenic insect-resistant crops.[2,5,6] Studies of insect populations have shown that resistance to insecticides, including Bt toxins, is most often attributable to a partially recessive mutation at a single major locus, and that the initial frequency of the resistant allele in unselected populations is low. A high dose in a Bt cultivar is one that is sufficient to make the resistant allele functionally recessive, so that insects heterozygous (RS) at the resistance locus do not survive when feeding on the cultivar. Refuges are non-Bt plants that serve to maintain homozygous susceptible (SS) insects in pest populations. For the refuge/high dose strategy to work, there must be a sufficient number and suitable spatial distribution of SS insects to ensure that the rare homozygous resistant insects (RR) mate with SS insects rather than with each other.

The refuge/high dose strategy has been implemented for Bt corn, potatoes, and cotton in the United States[2] and for Bt corn in Canada.[3] Currently available Bt corn cultivars appear to have a high dose of toxin with respect to the European corn borer *Ostrinia nubilalis*. Farmers who grow Bt corn must plant 20% of their land to non-Bt corn to serve as a refuge. The non-Bt corn fields must be planted at approximately the same time as the Bt fields, be of a similar corn cultivar, and be within approximately 0.5 kilometers (km) of the Bt fields. In Australia, where Bt cotton cultivars do not have a high dose of toxin with respect to the cotton bollworm *Helicoverpa armigera*, larger refuges are required.[4]

The U.S. Environmental Protection Agency established a working definition of a high dose in transgenic plants as “twenty-five times the protein concentration necessary to kill susceptible larvae,” and described five procedures for testing whether this criterion has been met.[2] A rough guideline for a high dose that can be used in preliminary assessment of transgenic plants has also been suggested.[7] These authors surveyed the toxin titers of Bt corn, cotton, and potato cultivars that appear to have a high dose based on field performance and noted that these cultivars have titers of at least 0.1–0.2% soluble protein or 1–2 ng/mg fresh weight (see also Table A2 in Ref. 2).

OPTIONS FOR USING MULTIPLE TOXINS

Larvae of Lepidoptera (moths and butterflies) are the target pests for the Bt corn and cotton cultivars that have been released so far and for numerous other Bt crops that are under development. For most lepidopteran pests, there are several Cry toxins that are of sufficient toxicity to achieve a high dose in Bt cultivars. Genetic engineering programs thus face the question of how best to utilize multiple toxin genes. Among the options are sequential release, mosaics, and pyramids. These options have been analyzed using simulation models that incorporate factors such as refuge size, the relative mortality of SS, RS, and RR insects, and the initial frequency of the R allele.[5,6] Two very robust and important conclusions are supported by simulation analyses of most sets of conditions:

- Pyramiding two toxin genes within a single cultivar provides substantially more total years of plant protection than either sequential release of the two genes (i.e., releasing the second gene after the pest
population has adapted to the first) or simultaneous use of two cultivars, each with a single gene, as a mosaic. Maintaining refuges and using high-dose plants substantially delays the evolution of pest resistance in all three of the above options.

Toxins that are pyramided in a cultivar should be sufficiently different in their properties to make it unlikely that a single insect mutation would result in the loss of effectiveness of both toxins. Cry toxins must bind to particular brush border membrane proteins of the midgut epithelium as one step in their mode of action. The most common basis of insect resistance to Cry toxins are mutations that result in a change in the binding properties of these membrane proteins. Competitive displacement assays of toxin binding to brush border membrane vesicles can be used to identify toxins that do not share binding sites and are therefore suitable for pyramiding. Such assays have generally shown that toxins highly similar in amino acid sequence, such as Cry1Ab and Cry1Ac, compete for the same binding sites, whereas less similar toxins do not.

Broad-spectrum cross-resistance to Bt toxins highly dissimilar in amino acid sequence has been observed only in three lepidopteran species and appears to be caused by resistance mechanisms other than altered binding. However, alleles conferring such cross-resistance are apparently rare, and there are few circumstances under which cross-resistance would result in a pyramid failing in fewer generations than sequential release of two toxins. Cotton cultivars with two pyramided Cry toxins are under development in the United States and Australia.

**MAINTAINING REFUGES**

Resistance management plans in the United States, Canada, and Australia specify the size and locations of refuges that farmers must maintain. Developing countries will generally need to take a different approach to resistance management, due to smaller farm size and limited extension services. In the case of Bt cotton in China, where the principal pest (H. armigera) feeds on many wild and cultivated plant species, it has been argued that non-cotton host plants will provide adequate refuges. Refuges comprised of alternative hosts are not an option for monophagous pests such as the yellow stem borer Scirpophaga incertulas, the most important lepidopterous pest of rice in tropical and subtropical Asia. In such cases, innovative approaches to maintain refuges will need to be developed. For example, governments can increase the probability that some farmers will grow non-Bt cultivars if they restrict the number of popular cultivars

---

**Fig. 1** How the refuge/high dose strategy works to delay the increase in highly resistant insects (RR) in a pest population. The strategy assumes that the dose in the Bt cultivar is sufficient to make the R allele functionally recessive, and that the initial frequency of R is low (<10⁻³). (Modified from Ref. 7.)
that are released in Bt form.\textsuperscript{[7]} Farmers who grow non-Bt cultivars would in effect provide refuges for neighboring farms. The non-Bt farmers may in turn benefit from the Bt cultivars grown by their neighbors, because local pest populations may decline substantially in areas where large proportions of fields are planted to Bt cultivars.\textsuperscript{[10]}

Although it is likely that some fields will be planted to non-Bt cultivars in areas where Bt cultivars become available and refuge requirements are not enforced, these fields may be relatively few in number. This highlights another important advantage of cultivars with two pyramided toxins: Such cultivars require smaller refuges. If both toxins are produced at a high dose, then insects able to survive on the cultivar (i.e., an insect homozygous for resistance alleles at two loci) will be extremely rare and thus fewer susceptible insects will be required to reduce the chances of resistant insects mating with each other.

\section*{CONCLUSION}

The United States, Canada, and Australia have implemented stringent resistance-management strategies to delay the adaptation of pest populations to Bt crops, and these strategies appear to be working. There have been no reports of outbreaks of Bt-resistant pests in these countries since the release of Bt crops in 1996–97. Developing countries may not be able to enforce the use of refuges to the same degree, but can still promote the sustainable use of Bt crops by instituting careful standards for Bt cultivars and limiting the number of popular cultivars that are released in Bt form. For crops in which the target pests are monophagous, it is particularly useful to release Bt cultivars with two pyramided toxin genes—both expressed at a high dose—because such cultivars require smaller refuges.

Transgenic Crop Plants in the Environment

R. James Cook
Washington State University, Pullman, Washington, U.S.A.

INTRODUCTION

In nearly two centuries of agricultural research, no single technology has offered more benefits and less risk to the environment than the transgenic technologies used to develop disease-, pest-, and herbicide-resistant or -tolerant crop plants. Historically, the negative effects of crop production systems on the environment have been the result of the tillage, pesticide applications, and fertilization used to grow crops, and not the direct effects of crop plants themselves on the environment. The use of a transgenic glyphosate-insensitive EPSP gene makes it possible to reduce or eliminate tillage; the use of Bt genes for insect resistance in cotton and corn, and coat-protein gene resistance to viruses in squash and papaya make it possible to reduce the use of pesticides for these crops. The use of just eight transgenic varieties of crops based on herbicide tolerance or insect or virus resistance reduced the total use of pesticides in the United States in 2001 by an estimated 20 million kilograms (46 million pounds). Moreover, crop plants genetically protected from pests and diseases are healthy, and therefore less likely than pest-damaged or diseased plants to leave nitrogen unused in the soil to leach into groundwater. In addition, they return more organic matter to the soil, which improves soil structure.

Scientists have rigorously focused on public concerns over the possible negative impact of transgenic crops on the environment, including negative effects on non-target organisms. Thus far, the potential negative environmental effects of so-call input traits (i.e., traits that moderate crop growth and disease), remain unconfirmed, inconsequential, or disproved. On the other hand, more research and experience will be needed on possible environmental effects of so-called output traits (i.e., traits that affect end-use products—say, that can convert a food crop into an industrial or medicinal crop). Crops with output traits are not yet in commercial use. Meanwhile, the continued adoption of transgenic plants with their novel input traits is fully consistent with the goals of sustainable growth in agriculture.

AGRONOMICAL USEFULNESS OF TRANSGENES

Transgenic crop plants were grown on 50 million hectares (130 million acres) worldwide in 2001.\(^1\) About two-thirds of the area planted to these crops is in the United States, followed by acreage in Argentina, Canada, China, South Africa, and Australia. More than 99% of this acreage involves the use of just two agronomically useful genes: 1) a glyphosate-insensitive EPSP gene used to make varieties of soybean, canola, and cotton insensitive to the herbicide Roundup\(^3\); and 2) variations on a Bt gene for production of a protein lethal to certain insects, used to make corn resistant to the European corn borer and corn earworm, and to make cotton resistant to the cotton bollworm, pink bollworm, and tobacco budworm. These genes are from bacteria widely distributed in the environment. The remaining <1% of the area planted to transgenic crop plants grow varieties of squash in the eastern United States and papaya in Hawaii, each transgenic for resistance to one or more of their insect-vectored viruses using the coat-protein gene of that virus.\(^2\)

The traits conferred by these agronomically useful transgenes are commonly referred to as input traits because their use results in a change in the inputs needed to grow the crop. Traits conferred by transgenes intended to improve end use or add value to the harvested product are termed output traits, but are not yet in commercial use. The rapid adoption of agronomically useful genes is not without precedent. Dwarfing genes Rht-B1b and Rht-D1 for reduced height in wheat and Sd2 for semidwarf growth habit in rice (introduced by conventional plant breeding) swept into worldwide use in the 1960s. These genes changed the harvest index (ratio of grain/grain + straw) of the plants from about 0.3 to nearly 0.5, thereby sparking what became known as the green revolution. In each of these examples, it is important to understand that, whereas the same or very similar genes are used worldwide, the varieties of wheat, rice, corn, soybean, cotton, and canola with these genes commonly number in the hundreds or thousands. Different varieties are needed for different end uses, and to ensure adaptation of the crop to the local climate, environmental stresses, and diseases. Many if not most of the currently grown transgenic varieties were developed by conventional breeding, wherein the transgene of interest was first introduced by transformation into one line (usually a line easily transformed) and then transferred by standard backcrossing into another line with the desired quality traits, and agronomically adapted to the area where it would be grown. Varieties with transgenes are subjected to the same
rigorous performance evaluations applied to conventional varieties before their release for commercial use.

ENVIRONMENTAL CONCERNS ABOUT TRANSGENIC CROPS

The development of transgenic crops has led to concerns over the possible effects of these crop plants or their new traits on non-target organisms in the environment. Assessments of risk have typically but incorrectly assumed that all factors in the cropping system remain the same except for the replacement of a conventionally bred variety with a transgenic variety. The adoption by farmers of any new variety is invariably accompanied by many modifications in crop management, including changes in date of planting, how or whether the soil is cultivated prior to planting, use of pesticides, and crop rotation. The use of a soybean variety with the glyphosate-insensitive EPSP gene results in the use of Roundup® in place of a mixture of herbicides, and may also result in elimination of pre-plant and postplant cultivation of the soil. The use of a corn hybrid with the Bt gene rather than one without it may also eliminate the need for one or more insecticide treatments and will almost certainly result in greater mass of hardy corn stalks left as field residue, due to reduced European corn borer damage. Consideration of the environmental effects of a crop or gene—whether transgenic or not—must thus be in the context of the cropping system as a whole.

Larvae of the monarch butterfly feed on pollen grains that collect on the leaves of milkweed plants within and outside corn fields. Concern for these insects arose when a laboratory test showed that larvae have higher mortality when fed pollen from a corn hybrid with the Bt gene than when fed pollen from a corn hybrid lacking the Bt gene. The risk was examined under field conditions in the context of different cropping systems, management practices such as planting date, weed control, and use of insecticides had large effects on monarch populations, whereas Bt-corn pollen from current hybrids had only negligible or no effect on Monarch populations. Gene transfer because of outcrossing has been raised as an environmental concern specifically for transgenic crops. There are two kinds of concerns: 1) gene transfer by outcrossing from a transgenic crop in one field to a conventional variety of that same crop species in a neighboring field; and 2) gene transfer to a wild or weedy relative of the crop. The transfer by gene flow of input traits between varieties of the same crop raises mainly economic issues, such as when a transgene occurs at some frequency in a crop intended for certification as organic, or when crop plants produced from seed left in the field (volunteers) are resistant to an herbicide intended for use in that field. The transfer by gene flow of an output trait between varieties of the same crop could raise safety issues for human health if the trait expressed in a food crop such as corn or soybean is intended for industrial use only. Geographic isolation or obligatory self-pollination to prevent gene transfer will probably be a prerequisite for production of these kinds of crops.

Gene transfer between related species is a rare event, and fertile hybrids produced by such outcrossing are rarer still. Wheat hybridizes with jointed goat grass, its weedy relative common throughout the wheat-growing Great Plains and Pacific Northwest of the United States, but after growing dwarfed wheat varieties in these regions for 40 years, no evidence exists for natural transfer of a dwarfing gene to jointed goat grass. In the great majority of cases, transfer of a gene agronomically useful in a cropping system will provide little or no survival value to that same plant or its wild relatives in an unmanaged or natural ecosystem. Gene transfer is a moot issue for crops grown where there are no wild or weedy relatives (e.g., corn, soybeans, and cotton in the United States) but can conceivably be an issue for corn grown in Mexico within range of pollen flow to its native progenitor, teosinte, depending on the trait.

The adoption of dwarfed varieties of wheat and rice was driven by the quest for higher yields to feed the growing world population. In addition to greater use of nitrogen fertilizer, which continues to have environmental consequences, the denser crop canopy and lush foliage typical of these cropping systems also led to increased pressures from insects and plant diseases. Where no useful genes for resistance to these pests have been available, or where evolution of the pest into new virulent strains has occurred faster than breeders could develop resistant genotypes of the crop, achieving the high-yield potential of these varieties continues to depend on pesticides.

ECONOMIC INDICATORS FOR TRANSGENIC CROPS

The adoption of crop varieties with the glyphosate-insensitive EPSP gene and a Bt gene is driven by the quest to increase efficiency through decreased cost of production, although in some cases yields have also increased. These cost-cutting measures are occurring on two fronts: 1) in use of less or no tillage (no-till), except as required to fertilize and plant the crop; and 2) in use of less pesticide or replacement of several pesticide applications with a single, lower-cost, more effective pesticide. Although driven by economics, these changes are also good for the environment. The use by U.S. farmers in 2001 of eight transgenic crop varieties with a Bt gene for insect resistance, the EPSP gene for Roundup® tolerance, or
coat-protein gene for virus resistance reduced total pesticide use in the United States by an estimated 20 million kilograms.\(^5\)

Of the 75.5 million acres of soybean grown in the United States in 2001, 70% were planted to varieties with the glyphosate-insensitive \(\text{EPSP}\) gene, and therefore relied on Roundup\(^6\) as the main or only herbicide for weed control.\(^6\) Nearly 70% of the U.S. cotton crop in 2001 was planted to varieties with the \(Bt\) gene for resistance to insects. The trend worldwide because of one or two \(Bt\) genes is to reduce the need for insecticides on cotton from 12–15 applications per season to only two or three. Moreover, stacking two slightly different \(Bt\) genes in the same plant, as now done with cotton, can greatly delay if not prevent the pest from adapting to this mechanism of plant defense. About one-fourth of the U.S. corn crop is now produced with hybrids with the \(Bt\) gene. Due to a combination of new genes for pest resistance and integrated pest management, wherein pesticides are applied based on predictive models and decision guides, the global market for pesticides peaked in the 1990s at about $30 billion, is now at about $20 billion annually, and is decreasing at a rate of about 2–3% per year (Ganesh Kishore, personal communication).

**CONCLUSION**

The negative impact of agriculture on air and water quality results almost exclusively in dust and sediment in water from cultivated land. Sixty percent of the 5.5 million acres of soybean double-cropped with wheat in the United States are now seeded directly (no-till) into wheat stubble.\(^7\) Of the 70 million acres of full-season soybean in 2001, 31% were direct-seeded into undisturbed soil and residue of the previous crop, usually corn. Of the 80 million acres of corn planted in the United States in 2001, 18% was direct-seeded. The European corn borer survives in corn stalks left on the soil surface, and is therefore a greater risk in direct-seed than in plow-based cropping systems. The European corn borer does not survive in \(Bt\) corn, however.

No-till cropping systems also result in other changes beneficial to the environment, including greater diversity of soil flora and fauna due to buildup of organic matter; greater water infiltration during intensive rains or snowmelt; more or better habitat for birds and other wildlife; and greater sequestration of carbon dioxide, one of the major greenhouse gases identified with global warming.\(^8\) These outcomes are made possible by continual improvement in crops and crop management. The current adoption of transgenic plants with their novel agronomic traits is an important part of this continuum and is fully consistent with the goals of sustainable growth in agriculture.

Transgenic Crops: Regulatory Standards and Procedures of Research and Commercialization

Qifa Zhang
Huazhong Agricultural University, Wuhan, P.R. China

INTRODUCTION

The estimated global area of transgenic or genetically modified (GM) crops reached 52.6 million hectares in 2001.[1] The rapid growth of the area planted to GM crops in both developed and developing countries strongly indicates that GM crops are welcome by growers and consumers alike. Utilization of transgenic crops will be a vital alternative to provide the world with adequate food and other agricultural products.

Although there have been widespread controversies regarding many safety aspects of transgenic plants as crops and food, there is an increasingly strong belief that transgenic plants can provide safe crops and food. This is because, in reality, transgenic technique does not pose any higher risk than traditional breeding methods to the safety of the crop products, and also because of the rigorous governmental regulations implemented by the countries that conduct transgenic research and grow GM crops. This article presents a brief overview of the regulatory standards and procedures for the environmental release and commercialization of GM crops.

REGULATORY STANDARDS AND PROCEDURES FOR TESTING AND CULTIVATING GM CROPS

The development of a transgenic crop consists of the following stages: laboratory research, confined field tests, environmental release, and commercialization. Governmental regulations in general address the following concerns in the process of commercialization of GM crops:

- Is the transgenic plant safe for the environment?
- Is the transgenic plant safe for agriculture?
- Is the transgenic plant product safe for use in foods, feeds, or other consumption?

Several strategies have been widely adopted in evaluating the safety of GM crops and foods. One of the strategies is based on the concept of substantial equivalence.[2] This approach acknowledges that the goal of the assessment is not to establish the absolute safety of GM crops and foods, but to evaluate their level of safety relative to their traditional counterparts, where such counterparts exist. Another important strategy commonly used in regulation is that the evaluation be done on a case-by-case basis.

For safeguarding the use of transgenic crops, science- and risk-based regulatory standards have now been established and implemented in many countries, and are being developed in many others. It should be noted that governmental regulation standards are also frequently bound to international agreements. Although there is substantial scientific commonality in the regulatory standards, the procedures followed in one country may be very different from those in another country. The cases of two countries, the United States and China, are given below as examples for demonstrating the common ground and differences in regulation of GM crops.

The United States was the first country to establish functional regulatory machinery for the biosafety of transgenic crops. A coordinated regulatory framework was set up in 1986 that assigned the responsibility to the Environmental Protection Agency (EPA), the U.S. Department of Agriculture (USDA), and the Food and Drug Administration (FDA), based on existing regulatory authorities of the U.S. government. A good starting point for information about regulation in the United States is the Web site “United States Regulatory Oversight in Biotechnology—Responsible Agencies—Overview” (http://www.aphis.usda.gov/ppq/biotech/usregs.html). The basic premise for regulation of GM crops is that such crops shall not be fundamentally different from unmodified organisms or those produced by conventional methods. The key principle adopted by the regulatory framework is that it is the product, rather than the method of producing the product, that should be regulated.

The regulatory body of the USDA is the Animal and Plant Health Inspection Service (APHIS). This agency regulates the importing, transportation, and field testing of GM crops and determines the likelihood of a transgenic plant having negative agricultural or environmental effects (http://www.aphis.usda.gov/ppq/biotech). For common crops and traits, researchers need only notify the agency of their intention to transport or field test a transgenic plant. The researcher is responsible to ensure
that the gene introduced meets certain technical criteria. For less common crops and for genes or traits that may pose greater risk, the researchers are required to file formal applications for permission to transport or plant the materials. Measures are required in field testing to prevent the spread of the transgene to the environment or into the food supply. Before commercializing a transgenic plant, the developer petitions APHIS for nonregulated status, which requires data on the introduced gene construct, plant biology, likely effects on the ecosystem, and field test reports, as well as data and information for any unfavorable effects. APHIS also has the authority to halt the sale of the GM crop if there is evidence that the GM crop is becoming a pest.

The FDA has authority to determine the safety of foods and food ingredients based on the concept of substantial equivalence, and relevant information can be found at the Web site (http://www.cfsan.fda.gov/~lrd/biotechm.html#label). The FDA adopts a voluntary consultation process with the GM crop developer, and reviews safety and nutritional data. If the introduced gene is from a known allergenic source, the GM food is required to be assessed for allergenicity. The FDA also has the authority to order the GM food’s removal from the market, if there is evidence that it is unsafe.

The EPA regulates transgenic plants that contain plant-incorporated protectants, including plants engineered for insect or disease resistance that the agency refers to as plant pesticides (http://www.epa.gov/pesticides/biopesticides/). This is implemented by granting an experimental use permit for testing, plant propagation registration, and full commercial registration, based on extensive reviews of data for the plant pesticide including its biochemical characteristics, toxicity, and environmental effects. The agency may require a resistance management plan in order to prevent or slow the development of resistance in the target pest. The EPA regulates herbicides, but not herbicide-tolerant plants. In the case of engineering a plant for herbicide tolerance, herbicides must be registered for a new use.

In addition to regulation at the federal level, many states in the United States also apply regulations on GM crops that require additional review and approval at the state level. Moreover, most research institutions have biosafety committees that monitor potentially hazardous transgenic research and ensure compliance with biosafety procedures.

In China, the biosafety of GM crops is regulated by the Ministry of Agriculture (MOA) (http://www.agri.gov.cn/ztzl/2001/0820/0820.htm). The MOA regulates the research, development, field tests, environmental release, and commercialization of GM crops. The MOA also regulates the import of GM crops and their products.

The process from laboratory research to commercialization of GM crops is divided into four stages in the Chinese regulation framework: laboratory research, confined field tests, environmental release, and product demonstration and commercialization. An MOA biosafety committee is responsible for reviewing the applications filed by researchers. In this system, notification of the MOA is required for transgenic research that may pose higher risk. For conducting field tests of a transgenic plant, a formal application must be filed with the MOA, which will be reviewed by the biosafety committee; a permit will subsequently be issued. In filing this application, the researcher is required to provide data about the gene construct, biology of the plant, test site, measures of confinement, and data to be collected. After a two-year field test, the transgenic plant can advance to environmental release when another application is filed with the MOA, submitting all data gained in the field test. Experimentation of environmental release in general will be conducted in another two consecutive years, after which another application should be filed with the MOA to advance the transgenic plant to product demonstration in large scale. At the end of the product demonstration, which usually requires two years to complete, the researcher can apply for a biosafety certificate for commercialization, which may require extensive data and comprehensive reviews. The transgenic plants can be used as parents for breeding purposes only when the biosafety certificate is issued, and the progenies from crosses with the transgenic parent must undergo the product demonstration procedure again and reapply for the biosafety certificate.

Information can also be found at Web sites for regulatory standards and procedures of the European Community (http://www.biosafety.be/Menu/BiosEur.html) and Japan (http://www.s.affrc.go.jp/docs/sentan/).

**LABELING OF GM FOODS**

Labeling of GM foods is a widely debated issue in many parts of the world. Although different countries’ regulatory standards (described in previous sections) address all concerns of consumers and thus provide strong assurance for food safety, there are still diverse opinions about the necessity of labeling GM foods. Again, countries are divided over requirements and procedures for labeling the GM foods.

As described in the previous section, food safety in the United States is regulated by the FDA. The FDA requires that all labeling be truthful, informative and not misleading, and identifies no characteristics of the GM food would justify labeling it as a special class. The FDA
requires labeling for GM foods in the same way as for other foods, including information about the composition, nutrition, and allergenicity concerns, but does not require special labeling of GM foods. Additional voluntary labeling is allowed, provided that it is truthful, informative, and not misleading. The FDA has recently developed industry guidance on voluntary labeling.

In Japan, implementation of new regulations on GM food labeling was initiated in April 2001 (http://www.maff.go.jp/soshiki/syokuhin/hinshitu/organic/eng_yuki_top.htm). According to the authority, labeling is not for safety concerns but for consumers’ right to choose or right to know. The labeling is implemented according to a positive list system, in which a committee is formed in the Ministry of Agriculture, Forestry, and Fishery (MAFF) to review the positive list of foods that should be labeled. In 2001, 15 soybean products and nine corn products were listed. The regulation requires that the food should be labeled if the DNA/protein of the transgene can be detected, the raw materials are among the top three constituents, and the GM materials are 5% by weight.

In China, labeling of transgenic organisms was enforced in March 2002 (http://www.agri.gov.cn/xxfb/2002/0107/dt0110-2.doc). Labeling is administered by the MOA, and regulation covers the transgenic organisms included in a list that is updated from time to time. The current list includes soybean, corn, rapeseed, cotton, and tomato. It regulates not only GM foods, but also seeds and other products from GMOs that are sold in the marketplace.

In Europe, a series of regulations applies concerning traceability and labeling of GMOs and of GMO food and feed products. (http://www.biosafety.be/Menu/BiosEur4.html). The regulation requires labeling of products consisting of or containing GMOs, foods and food ingredients (including food additives and flavorings produced from GMOs), feed materials, and compound feeding stuffs and feed additives produced from GMOs placed on the market in accordance with European Community legislation. Traceability requires that information about GMO products placed on the market be transmitted from one operator to the other in transaction, and that operators have in place systems and procedures to allow the identification of persons involved in the transactions for a period of five years.

CONCLUSION

Functional regulatory machinery has been established in many countries in the last decade. However, regulatory standards and procedures are still evolving, even in countries with a relatively long history of GM crop cultivation. With rapidly accumulating large-scale adoption and public recognition of the advantages of GM crops, it is believed that goals, standards, and procedures of regulation will gradually become globally harmonized and will promote the utilization and exploitation of the full benefits of GM crops, in order to better meet the demands of the ever-increasing world population.

INTRODUCTION

This article concerns transposable elements and their role in altering genes within the genome. Like swimmers in shark-infested waters, genes in genomes with active transposable elements or transposons lie ever susceptible to attack. Whereas transposons were discovered approximately 50 years ago, only recently has the magnitude of transposons’ roles in shaping genetic material been realized. It is now clear that the number of ways transposable elements can reshape genes and genomes is almost endless. Here we limit discussion to diversity caused by transposons in individual genes. Transposable element visitation can 1) alter the protein coding information, 2) alter the regulatory information, 3) increase gene number, and 4) potentially give rise to introns. Examples of each form of alteration are given below. Severe space limitations dictate that we limit our discussion to only general overviews and refer only to reviews and recent key papers. Interested readers are highly encouraged to peruse the literature for more detailed information.

WHAT ARE TRANSPOSABLE ELEMENTS?

Transposable elements or transposons were first described some 50 years ago by Barbara McClintock in her seminal studies in maize leading eventually to receipt of the Nobel Prize. Transposons are DNA sequences that can change position within the genome. While classified as transposons, these elements differ in many, fundamentally important, ways. For example, movement or transposition of the element varies, depending on the family of elements. In some cases, the so-called “cut-and-paste” elements, the transposon exits its original position and moves to a new site. Gene function at the original site is sometimes restored. In other cases (copy-and-paste), only a DNA copy of the element moves to a new site, whereas in other systems, RNA copies of the element are reverse-transcribed into DNA which then insert back into the genome. Elements differ in size, from the small miniature inverted-repeat transposable elements [5] [a few 100 base pairs (bp)] to elements greater than 10,000 bp. Finally, elements differ in abundance. Most significantly, it is now known that RNA-based transposons make up the majority of many genomes.

TRANSPOSONS ALTER PROTEIN CODING INFORMATION

A fascinating and likely evolutionarily important property of the cut-and-paste transposons is their ability to create small insertion/deletion polymorphisms within genes. Upon insertion, these elements duplicate host sequences, the size of which is family-specific. The duplication likely occurs via an initial staggered cut in the host DNA followed by DNA repair after insertion. Subsequent excision of these elements is imprecise, and one commonly finds DNA sequence alterations at the site of integration. These alterations usually involve insertion of part of the host duplication and are influenced by adjacent sequences.

Insertion/deletion (InDel) polymorphisms of the size made by transposons are quite common in plant genomes. Whether a particular InDel was, in fact, created by transposons or by slippage in DNA replication or unequal crossing over cannot be determined without complete pedigree information of the sequences in question. However, because the excision frequency of particular cut-and-paste elements can be extremely high (hundreds per generation in a single plant), it is quite probable that transposons are a major source of this type of variation.

Transposon-induced InDel variation likely is quite important in evolution. A particularly straightforward case in which transposon-induced InDel variation was useful for breeding programs comes from maize. A Ds (Dissociation) insertion into the shrunken-2 (Sh2) gene was isolated almost 35 years ago at Purdue University. Sh2 encodes one subunit of the allosterically controlled...
enzyme, ADP-glucose pyrophosphorylase. Fortuitously, the insertion resided within a region of the gene encoding an allosteric binding site of the enzyme. One excision event, leading to a 2 amino acid insertion, greatly reduced inhibition by an allosteric effector molecule and, in turn, caused a 30% increase in maize seed weight.[8]

**TRANSPOSONS ALTER GENE REGULATION**

One of McClintock’s basic tenets posited that transposons are involved in gene regulation. This belief led to her nomenclature whereby transposons were termed “controlling elements.” It is now quite clear that transposons do not usually act as the controllers of gene expression (promoters, enhancers, and such) that we typically associate with gene regulation (but see below). Nonetheless, there exist ample examples in the plant literature in which a transposon has become intimately associated with control of gene expression.

One of the earliest examples concerns the A1 (anthocyaninless-1) gene in maize and the transposon system (Spm/En—suppressor-mutator/enhancer).[6] Spm/En is one of several two-element systems in the maize genome. One element, often unable to move on its own, resides at the gene in question and inhibits gene function, whereas a second, autonomous element can activate both itself and the first element to transpose. Specific to the Spm/En system, introducing the autonomous element (Spm/En) normally leads to mutability (transposition) of a nonautonomous element (dSpm/I) but also, in some cases, to inhibition of a leaky phenotype conditioned by the dSpm/I insertion when Spm/En is not present. One series of mutable alleles arising from the a1-m2 allele exhibits a different set of phenotypes. Here the mutant alleles actually condition some gene activity in the presence but not in the absence of the Spm/En element. Molecular mapping showed that the dSpm/I lies in the promoter of the A1 gene and appears to have commandeered control of gene expression. Additional insertions into the A1 promoter of nonautonomous dSpm/I and Mutator elements alter how the A1 gene responds to upstream regulators as well as its tissue specificity. Numerous cases have now been reported of ‘Mu-suppressible’ alleles, in which mutant phenotypes caused by Mutator insertions in maize genes lose their mutant phenotype as the transposon becomes inactivated, both somatically and gametally. In several cases, the now-functional gene transcripts initiate within the inactivated transposon.[9] Outward-reading promoters have also been reported in the termini of Ac/Ds elements, suggesting that the ability to seize control of how a target gene is regulated may be a widespread feature of transposons.

**TRANSPOSONS INCREASE GENE NUMBER**

There exist now a number of reports in the plant literature of various transposable elements capturing and moving gene sequences within the genome. The copy number of these genes then increases along with the transposon copy number. For example, Talbert and Chandler[10] identified a sequence in a particular Mutator element with unambiguous similarity to a maize gene. Similarly, the maize retrotransposon Bs1 contains portions of at least three maize genes.[1,11] The tendency of Ac/Ds elements to move to nearby sites has allowed the formation of what are termed “macrotransposons.”[4] If the outside borders of two, closely linked Ds elements in the same orientation are recognized in a single transposition event, the two elements plus the host DNA lying between them become a single transposon. Recently, a fundamentally different type of transposon was described in plants.[11] These elements, termed Helitrons (Fig. 1), lack terminal repeats, do not duplicate host sequences upon insertion, leave host junction sequences entirely intact, and exhibit very little sequence similarity among family members. They are, however, very good at capturing genes or parts of genes. For example, 12 pseudogenes were found in one, 17.8-kbp maize Helitron. Two pseudogenes were found in approximately 10 kbp of another maize Helitron. While analysis of these elements is only beginning, evidence favors the

![Diagrammatic representation of the newly described transposable elements termed Helitron. Motifs common to all Helitrons are highlighted.](image-url)
notion that the elements preferentially target active genes for insertion through DNA strand invasion. Moreover, because the termini of the element are not well defined, continued DNA replication through the element can allow for capture of adjacent gene sequences.

Note that transposons of diverse types (DNA-mediated cut-and-paste, RNA-mediated copy-and-paste, as well as the newly described *Helitrons*) all have the ability to capture genes while traveling through the genome. That gene sequences can be multiplied and moved throughout the genome provides a ready explanation for the formation of gene families. Whereas the existence of gene families has been known for decades, they are becoming much more apparent with the recent massive sequencing projects. Because the number of members within different families differs dramatically, it is likely productive to consider transposons as the underlying multiplying mechanism. This is particularly relevant in those cases where polyploidy or unequal crossing over is clearly not causal. Furthermore, the fact that maize inbreds actually differ in the presence/absence of genes in various linkage groups strongly suggests that gene capture and movement is prevalent in modern genomes.

**TRANSPOSONS CAN CAUSE INTRON FORMATION**

A truly remarkable property of at least some transposons is their ability to form introns. This has been documented for two cut-and-paste transposon systems, *Ac/Ds* and *Spm/En*, and, with *Ds*, for both orientations of the transposon relative to the gene it is inserted into. These two facts alone suggest that transposon-induced intron formation is biologically relevant. Significantly, the mechanism by which transposons synthesize introns provides a ready explanation for a hitherto puzzling observation concerning exon/intron borders.

Typical nuclear introns begin with the virtually invariant dinucleotide GT and end with the invariant sequence AG. Whereas there are no apparent constraints on the exon sequences adjacent to introns, unexplainably, exons usually begin with GT and end with AG as well. An explanation for the dinucleotide exon termini, however, became apparent from analysis of transposon-derived introns. As noted above, most transposons duplicate host sequences upon insertion. In order for a transposon insertion to form an authentic intron, the created duplication must involve either one or both of the intron terminal dinucleotides GT and AG (see Ref. [13] for details). Hence the fact that nuclear exons often begin with GT and end with AG is explained by a mechanism of intron origin involving duplication of host sequences.

If transposons truly are important in creating new introns, could a system that creates introns in preexisting genes be favored in evolution? We note that many introns enhance gene expression, in some cases, as much as 70-fold. Perhaps the important form of genetic variation created by transposons—and the reason they are tolerated in modern genomes, and even favored—concerns their effects on gene regulation. If so, McClintock may have been right after all (again). Transposons may, in fact, have roles as genuine, gene-controlling elements. That control, however, may be more far-reaching in its variety than even she had imagined.

**CONCLUSION**

While transposons have been known for almost one-half of a century, their relevance in shaping genomes, causing mutations, increasing gene copy number and controlling gene expression is only presently being realized. It is now clear that transposons make up much of the repetitive DNA sequences, create mutations in coding information, multiply genes through sequence capture and movement, and alter gene expression by insertion into promoters and possibly through creation of introns.

INTRODUCTION

Most plants are covered with an assortment of structures, varying in morphology from hairlike to globular. Such structures, usually originating from the plant epidermis and projecting outward from the plant, are termed trichomes. They can be found on any plant part, and several different types of trichomes are sometimes found on the same plant surface. At the microscopic level their varied morphologies are truly amazing.

Trichomes may be classified by various criteria; however, they are generally either glandular or nonglandular with regard to function, depending on whether they produce a secretory product. The cotton fiber represents one extreme of a nonglandular trichome; the large, multicellular glandular trichomes found on many species are examples of the other extreme. The economic value of both fibrous trichomes and the contents of glandular trichomes is large. Furthermore, the negative impact of trichomes or trichome products that cause health problems for animals (including humans) is significant.

TRICHOME ANATOMY AND DEVELOPMENT

Plant trichomes have been the subject of at least three entire volumes.[1–3] Several reviews on trichome anatomy and development are available (e.g., Ref. 4). The term trichome has generally been meant to include only epidermal appendages originating from the plant epidermis. Root hairs meet this definition and are beginning to be considered trichomes by some molecular biologists and plant anatomists.[4] Trichome-like structures such as the glandular protrusions of several species of Hypericum may not originate from epidermal cells, but are considered trichomes by some.

Both nonglandular and glandular trichomes range from unicellular to multicellular (uniseriate, biseriate, or multiseriate) (Fig. 1). Nonglandular trichomes can have many forms, depending on the species, and more than one type can be found on a single species. They can be filamentous, stellate, scalelike, branched, tufted, and combinations of these morphologies. Some are only warty protrusions from epidermal cells. At maturity, the cells of most nonglandular trichomes are dead, with the cell wall and cuticular thickness and composition providing textures ranging from stiff to soft. The cotton fiber is one of the more extreme morphologies of a unicellular, nonglandular trichome. These fibers arise from epidermal cells of ovules, reaching lengths of several centimeters.

Glandular trichomes can be of several types, depending on their morphology and on what they secrete, accumulate, or absorb. The typical multicellular peltate glandular trichome has a specialized secretory cell or cells that secrete products into the space between the cuticle and cell wall of the head cell(s) (Fig. 2).[5] Very early in development of a plant organ, an epidermal cell begins differentiating and dividing into such a trichome.[6] The cells of this structure are initially very similar, but differentiate into stalk and head cells that apparently have different functions. Nevertheless, at maturity each cell type is normally filled with cytoplasm containing very small vacuoles, unlike most plant cell types with a large central vacuole. The apical cells of the head secrete material into the space between the cell wall and cuticle. The cuticle then swells to a balloonlike structure filled with secretory products over the terminal cells. There is good evidence that many of the compounds secreted by this type of trichome are synthesized only by trichome cells.[7,8] As glandular trichomes age, the cuticle may break, spreading the nonvolatile contents over the plant epidermis. In some species, a new cuticle can form to contain newly synthesized glandular products.

Other specialized types of glandular trichomes are salt glands and nectaries. Salt glands can be of several forms, including bladderlike cells in which salts are compartmentalized in a central vacuole, and epidermal cells that excrete salts into subcuticular spaces or onto the plant surface. Nectaries are glandular trichomes that excrete nectar. They are often associated with flowers, but can also be extrafloral.

The molecular genetics of trichome formation and development is beginning to be understood. More than 20 genes are involved in trichome formation in Arabidopsis, and much is known of the genetics of cotton fiber-specific promoters and the genes associated with cotton quality. Some of the genes involved in root hair development are the same or very similar to those involved in trichome development. Genes involved in biosynthesis
and secretions of glandular trichome-specific compounds are also being identified. Because glandular trichomes appear to be the only location for biosynthesis of many secondary compounds in plants, glandular trichome development and the biosynthetic pathways for these compounds appear to be genetically connected. Knowledge of the molecular genetics and biology of trichomes should eventually provide economic dividends by improving cotton quality and yields, as well as providing the basis for increasing the production of valuable glandular trichome products.

**ECONOMIC ASPECTS OF TRICHOME PRODUCTS**

Perhaps the most economically important trichome is the cotton fiber. This is the only trichome fiber crop. The contents of glandular trichomes are also often valuable. Table 1 provides a partial list of valuable trichome products. Glandular trichomes can produce many different types of chemical compounds, including terpenoids, alkaloids, and flavonoids. Essential oils (mostly terpenoids) of many plant species are associated primarily with glandular trichomes. Essential oils are important as flavorings and fragrances. Some specific trichome products, such as the antimalarial drug artemisinin, have high value as pharmaceuticals, and others contain the psychoactive compounds of tobacco and marijuana.

Trichomes of a few species contain compounds that are problematic for people and livestock. For example, certain nettles (e.g., *Cnidoscololus texanua* and *Urtica urens*) bear trichomes that cause a painful sting when touched, due to mild neurotoxins (e.g., leukotrienes). Contents of other glandular trichomes are poisonous if ingested in sufficient quantity. Some people are highly allergic to certain glandular trichome compounds such as the sesquiterpene lactones of some *Parthenium* species. These people

develop severe contact dermatitis by direct contact with the plant or by contact with windborne plant material.

**TRICHOME FUNCTION**

Plant species have evolved trichomes in response to both biotic and abiotic selection pressure. Glandular trichomes represent predominantly chemical strategies for dealing with this pressure, whereas nonglandular trichomes offer physical responses to environmental challenges.

The first contact that plant pathogens, insects, and herbivores have with plants is at the plant epidermis. The chemical contents of glandular trichomes are often highly biologically active against many of the biota from which the plant needs protection. The gland content or its exudate can act as a poison or repellent. It can also attract pollinators or other beneficial insects. Table 2 provides examples of the biological activity of some glandular trichome components. Note that a given compound can have multiple effects, depending on its concentration and the species affected. Glandular trichomes provide a means of concentrating these compounds in the proper place to come in contact with target organisms, while partitioning them from other plant tissues. In this manner, glandular trichomes can protect the plant from autotoxicity. They can also protect it from synthetic phytotoxins. For example, cotton is partially resistant to certain lipophilic herbicides used with this crop, due to partitioning of foliar applications of the herbicide into the lipophilic subcuticular spaces of glandular trichomes. Similarly, lipophilic insecticides can partition into glandular trichomes after foliar application, where they are protected from volatilization and degradation, resulting in increased efficacy.

At sufficient densities, nonglandular trichomes can shield a plant from direct sunlight in severe environments, such as alpine ecosystems. Certain nonglandular trichomes can also reduce water loss by shielding the plant epidermis from wind. However, smaller numbers of trichomes can make the boundary layer of photosynthesizing organs more turbulent as air passes over the epidermis. This can increase transpiration while facilitating photosynthetic gas exchange. The silicon content of some trichomes can be so high as to make the plant unpalatable to insects and other herbivores.

UV Radiation Effects on Phyllosphere Microbes

Thusitha S. Gunasekera
Michigan State University, East Lansing, Michigan, U.S.A.

INTRODUCTION

The leaf surfaces (phylloplane) of plants are characteristically colonized by epiphytic communities of bacteria, yeasts, and filamentous fungi. Among the different factors that affect microbial survival and growth in the phyllosphere, solar UV radiation (UVR) plays a central role. Colonization of plant surfaces by microorganisms therefore clearly depends on their ability to tolerate UVR stresses or to avoid such stresses by colonizing protected sites. More recently, UVR has received considerable attention because solar UVB wavelengths (290–320 nm) are increasing as a consequence of stratospheric ozone depletions. Current research has shown that variation in UVB radiation significantly affects many organisms and ecosystems including phyllosphere microorganisms.

CELLULAR DAMAGE AND REPAIR MECHANISMS

Only UVA (320–400 nm) and longer wavelengths of UVB (>290 nm) radiation penetrate to the terrestrial environment. UVR is absorbed by vital cell molecules such as nucleic acids and proteins, resulting in various forms of damage including the induction of pyrimidine dimers. UVR-induced lesions distort and deform the DNA helix and interrupt transcription, translation, and replication. However, photodamage by UVR is a wavelength-dependent process. UVA radiation causes indirect damage to DNA, proteins, and lipids through reactive oxygen intermediates. UVB radiation causes both direct and indirect damage because of strong absorption of shorter wavelengths of UVB by DNA. Although the absorption spectra of proteins vary greatly because of variations in content of aromatic amino acids, some proteins are directly vulnerable to UV damage.

Both prokaryotic and eukaryotic organisms have multiple DNA repair pathways. One of the most widely distributed repair mechanisms is photoreactivation (PR), in which pyrimidine dimers are photochemically removed through the mediation of an enzyme, DNA photolyase. Apart from PR, another important and conserved pathway for repair of UV damage to DNA is nucleotide excision repair (NER), which is found in eubacteria, archea, and eukaryotes. In this pathway, UvrABC endonuclease removes a short oligonucleotide encompassing the damaged bases, and the gap is ressealed with polymerase and ligase. Additional pathways for UV resistance, such as post-replication, recombinational repair processes, and recA and lexA-mediated inducible SOS stress responses also exist in both prokaryotic and eukaryotic organisms. These processes can quickly repair DNA damage, but they are error prone and so produce mutations.

RESPONSE OF PHYLLOSHERE MICROORGANISMS TO UV RADIATION

Available information suggests that large inter- and intra-specific variations in UVR sensitivity exist within phyllosphere microbial communities, with the UVB component of solar UVR being primarily effective in regulating microbial populations. Variation occurs on a range of scales. There is evidence that isolates from different geographic regions with contrasting UVB climate vary in UVB tolerance. Large variation was also noticed within the same site or locality. Pathovars of Pseudomonas syringae and strains within the pathovar syringae have shown large variability to tolerance of UVR. UVB radiation might, therefore, be an important factor influencing the differential survival of phyllosphere organisms and hence the species composition of the phyllosphere community. The effects of UVB radiation on the phyllosphere community colonizing over a commercial tea crop showed that the leaf colonization of Corynebacterium aquaticum and Xanthomonas spp was influenced by solar radiation and that during certain periods of the year colonization was significantly higher under a UVB-depleted environment than under the natural environment. These results were interpreted as seasonal fluctuation of microorganisms on leaves influenced by UVR. UVR-sensitive species or strains, however, can succeed by colonization on the phyllosphere during the less sunny period of the year.

Existence of marked variation in response suggests that mechanisms have evolved that moderate these potentially damaging effects. UVB levels on the plant surfaces are not uniform; mutual shading of the leaves, depressions, veins, and bases of trichomes provide some
protection against the UVB radiation. Colonizing in protected sites would be useful to avoid such high UV fluxes. The avoidance of UVR by colonization of the abaxial surfaces is thus an important strategy adopted by phyllosphere microorganisms.[5]

Phyllosphere microbes may reduce damage by reducing penetration to target molecules, especially nucleic acids in the nucleus. The most important component of UV protection is the production of UV-absorbing pigments. The putative role of pigments in protecting phyllosphere microorganisms against UVR is supported by the observation that significant numbers of microorganisms isolated from the phyllosphere are pigmented.[5] Phyllosphere yeasts such as Sporabolomyces spp., Rhodotorula spp., Sporidiobolus spp., Cryptococcus spp., and the common phyllosphere bacterium Erwinia herbicola are capable of producing carotenoids, which protect cells against UVA wavelength–induced reactive oxygen intermediates.

The third strategy for minimizing UVB effects is via the range of repair pathways available to correct primary UV damage. The importance of these pathways for epiphytic growth has been demonstrated for some phyllosphere microorganisms. The common phyllosphere bacterium P. syringae pv. syringae FF5 or of an insertional mutation within rulB in strain 8B48. The rulAB system is also able to promote UV-inducible mutagenesis, suggesting the functional relevance of rulAB and its important role in overcoming UVR stress in the phyllosphere.[8] Significantly reduced susceptibility to UV damage in the presence of white light is evidence for PR in the tested phyllosphere microorganisms[3] and in the common phyllosphere bacterium P. syringae.[9]

**Fig. 2** Response of Pseudomonas syringae pv. syringae FF5 (○), FF5/pPSR1 (☐, rulAB+), 8B48 (●, rulAB+), and 8B48A (■, rulBkm) to UV-B radiation. Cells suspended in saline solution were irradiated as previously described,[6] and survival was calculated as related to a non-irradiated control. Each point represents the mean (± the standard error of the mean) from three replicate experiments.
UV radiation effects on phyllosphere microbes

UV radiation can also alter the physical and chemical properties of leaf surfaces, with potential indirect effects on colonization of microorganisms on the phyllosphere. These indirect effects are largely unknown. To date, it is not known how UVR affects interactions between phyllosphere microorganisms with specific plant pathogens, but it is likely that such interactions will be complex, depending on host-mediated changes and direct effects on the microbes involved. However, increased understanding of UVR effects on interactions between phyllosphere microbes and pathogens offers the greatest opportunity for exploiting increased understanding of UVR effects on the phyllosphere. Success in controlling plant pathogens, insects, or the ice-nucleation active bacteria depends largely on the establishment of biocontrol agents on plant surfaces. Successful biological control agents should survive and persist in the target sites of the phyllosphere for a long time. UV-resistant strains can possibly be used to increase the efficacy on the phyllosphere. On the other hand, some bacterial pathogens’ epiphytic growth is critical for dissemination and their survival away from the host. Therefore, UVR responsible for regulating foliar diseases and more importantly UVR can be used to control UV-sensitive pathogens on plant surfaces.[10]

CONCLUSION

Available information suggests that phyllosphere organisms display inter- and intra-specific variation in response to UVR and increased UVB irradiation above ambient levels, resulting in alterations of the relative abundance and species composition of microorganisms in the phyllosphere. Increase of UVB radiation therefore may change the microbial balance and possible microbial interactions in the phyllosphere or important host-pathogen interactions. Existing information suggests that the ecological succession of phyllosphere microorganisms is in part driven by UBV radiation. Ecological studies also showed that UV tolerance is a prevalent phenotype among phyllosphere microorganisms and that DNA repair or UV-tolerant mechanisms are vital to the phyllosphere microorganisms for survival in this UVB-rich habitat.

UV Radiation Penetration in Plant Canopies

Richard H. Grant
Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

Sunlight—or solar radiation—is the ultimate source of all the energy that a plant receives throughout its life. Most would agree that the wavelengths of the solar radiation spectrum utilized by chlorophyll are the most important part of the sunlight reaching plants. There are, however, several other important wavebands of solar radiation that affect plant growth and development—among them, radiation in the ultraviolet (UV) waveband. Solar radiation in the UV band can affect the viability of spores and pollen, the mutation of plant cells, and the chemical composition of plant biomass. Consequently, changes in the intensity of solar radiation in the UV band may have significant impacts on agriculture. We are now experiencing changes in atmospheric ozone that change the intensity of the UV radiation received by plants. How intense that radiation is at the top of the plant canopy, how that radiation is distributed in plant canopies, and the duration of the intense radiation will define how UV radiation will affect crop agriculture.

WHY WORRY ABOUT UV RADIATION IN PLANT CANOPIES?

Solar radiation is largely in wavelengths that the eye can see, but ultraviolet (UV) radiation is in wavelengths shorter than the eye can see. Solar UV radiation reaching the earth’s surface is separated into two wavebands: a band from 320 to 400 nm called UV-A (ultraviolet-A), and the band from 280 to 320 nm called UV-B (ultraviolet-B), although some scientific organizations define 315 nm as the division between UV-A and UV-B. Because ozone is the primary absorber of UV-B in the atmosphere, changes in the ozone change the intensity of the UV-B radiation at the earth’s surface. Increased UV-B has the potential to decrease the productivity of agricultural crops and viability of spores and pollen in canopies. We will assume here that the plant surface of interest in the canopy could be any phytoelement at any orientation, including stalk, leaf, grain head, silk, or stamen.

ABOVE-CANOPY RADIATION ENVIRONMENT

To understand the penetration of UV radiation into the canopy, we must first consider the nature of UV radiation above the canopy. The atmosphere scatters solar radiation inversely proportional to the wavelength, resulting in more of the direct beam of solar radiation being scattered into the sky hemisphere in the UV than in longer, visible wavelengths. The fraction scattered into the sky, termed diffuse radiation, varies according to atmospheric conditions and solar zenith angle. On a clear day the sky diffuse fraction increases with increasing solar zenith angle, resulting in higher diffuse fractions at the top of plant stands early and late in the day than at midday and at low and mid-latitudes. Generally higher solar zenith angles at higher latitudes result in higher diffuse fractions at high latitudes than at low latitudes for any time of the day.

The slope and aspect of a surface such as a leaf affects the amount of UV-B received above the canopy (Fig. 1). Nonhorizontal leaves at the canopy top receive some diffuse and direct beam radiation reflected off both the canopy phytoelements and underlying soil surface. Irradiance decreases with increasing zenith angle so that leaves (or other phytoelements) perpendicular to the ground and canopy top (erectophile leaves, seed heads, and other vertical phytoelements) have minimal UV-B exposure. [1]

WITHIN-CANOPY RADIATION ENVIRONMENT

The irradiance in the canopy is the cumulative effect of the downward penetration of diffuse and direct beam radiation, the downward phytoelement-scattered radiation, and the upward scattering of radiation penetrating to and scattered from the soil surface and phytoelements below the level of interest in the canopy. The relative importance of each contributing component of the spectral irradiance in the canopy depends on the optical properties of the canopy phytoelements, the canopy density, and structure. [2]
Scattering in the Canopy

The radiation that is scattered from phytoelements and soil within and under the canopy (secondary scattering) depends on the incident radiation and the reflectance and transmittance of the phytoelements and the reflectance of the soil surface. The reflectance of adaxial and abaxial leaf surfaces of maize (*Zea mays* L.), soybean (*Glycine max* L. (Merr.)), common oats (*Avena sativa* L.), winter wheat (*Triticum aestivum* L.), and sorghum (*Sorghum bicolor* L. (Moench.)), as well as apple (*Malus* × *domestica* Borkh.) and Callery pear (*Pyrus calleryana* Dcne.) are nearly constant (0.05 to 0.10) throughout the UV-A and UV-B. There is no reported leaf transmittance in the UV for apple, Callery pear, maize, soybean, winter wheat, oats, or sorghum. The reflectance from soils is similar to reflectance from the leaves, with dry light-colored soils having an average UV reflectance of approximately 0.07. Because UV radiation does not penetrate through the plant leaves, the transformation of direct beam radiation to diffuse within the canopy is solely through phytoelement and soil surface reflections. In contrast to the UV-B waveband, leaf transmission and reflection are significant in the photosynthetically active radiation waveband (PAR), resulting in substantial secondary scattering in the canopy.

Downward Penetration in the Canopy

The downward penetration of UV radiation into the canopy varies spatially and temporally due to the distribution of plant phytoelements and the orientation of the elements. The vertical penetration is commonly considered to be the mean or median over time with sunlit or shaded periods, or horizontal space with sunlit and shaded areas.[12,3] If the direct beam radiation cannot penetrate the canopy to a point in the canopy space, then it is considered to be shaded.

The stand density (plants per unit area) influences the view of the sky and the probability of shading in the lower canopy. Low-density canopies typically have large gaps (breaks in the spatial continuity of vegetation) that allow diffuse radiation to penetrate directly to the base of the canopy at all times (in shade) and allow direct beam radiation on occasion (in sunflecks). The size and distribution of gaps depend on the phytoelement orientation, dimension, and clumping. Increasing gap size increases both the diffuse sky radiation received and the probability of the direct beam penetrating the canopy. Shaded areas in the canopy receive only diffuse radiation, and vary from having essentially no irradiance in very dense canopies with no gaps to nearly the same amount of radiation as coming from the sky above the canopy in open canopies (Fig. 2). Sunlit areas (sunflecks) within the canopy have UV-B irradiance varying from the fraction of the above-canopy direct beam UV-B to the global above-canopy UV-B irradiance as the gap increases in size or number (Fig. 2). In sunflecks, the PAR is enriched relative to the UV-B—especially for small gaps with minimal sky view.

For low-density canopies with large gaps, the UV-B penetrates to greater depths than the PAR as a result of the higher fraction of diffuse radiation than in the PAR. In these canopies the UV-B irradiance in shade is closer...
to that of sunlit regions than for PAR radiation. Consequently, shaded areas are enriched in UV-B relative to the PAR. Such enrichment is evident in young and old orchards. UV-B enrichment is evident in winter wheat, tall fescue (Festuca arundinacea Schreb.), and perennial ryegrass (Lolium perenne L.) canopies. Sunlit surfaces in an apple orchard[3] and in maize canopies[3,4] had UV-B levels similar to that above the canopy, whereas shaded surfaces had less UV-B than at the top of the canopy—varying with differences in sky view, diffuse fraction, and orientation.

Shading increases with increasing plant stand density and increased cumulative leaf area index (LAI) with depth in the canopy (Fig. 3). The shading in closed canopies (or high-stand densities) is primarily between-plant shading and produces relatively small areas of sunfleck at the stand floor (Fig. 3). In a maize canopy, three distinct radiation regimes were evident for surfaces at a height corresponding to a cumulative LAI of 1; a sunlit regime associated with direct beam penetration through a gap, a deep UV-B shade regime associated with small gaps nearby, and a light UV-B shade regime associated with large gaps nearby.[4] As depth in the maize canopy increased, the light UV-B shade regime disappeared and there was similar (small) penetration of UV-B and PAR. Similar changes in the frequency of gaps and the sunlit and shaded UV-B levels with depth in the canopy were found for winter wheat (Fig. 3). Planophile canopies such as alfalfa (Medicago sativa L.), white clover (Trifolium repens L.), and sorghum have infrequent gaps and equal or greater penetration in the PAR than UV-B radiation through scattering in the canopy.[5,6]

Changes in UV Penetration During the Growing Season

Crop canopies begin the season as sparse, low-density canopies. However, the vegetation in many crop canopies fills in (having LAI>1) over the course of the season to leave few gaps between plants at flowering or maturity. Consequently, the relative proportion of UV-B and PAR changes as the crop matures. UV-B penetration of low-density stands is typically greater than PAR because the sunlit regions receive approximately the same amount of PAR and UV-B, whereas the shaded regions receive significantly more sky UV-B than PAR. As the stand fills in, the overall penetration of diffuse sky radiation decreases—increasing the importance of secondary scattering in the canopy that is negligible for the UV-B and significant for the PAR. Consequently, over time the relative penetration of PAR increases compared with the UV-B, as documented for white clover and orchardgrass (Dactylis glomerata L.).[6]

CONCLUSION

The penetration of UV radiation into plant canopies is dictated largely by the amount of sky view created by gaps in the canopy. There is little scattering through or off canopy phytoelements within the canopy or off the ground at the canopy base. UV radiation levels in plant canopies are proportional to the size of the gap and view of the sky. Shaded regions near large gaps in the canopy have relatively high levels of UV radiation relative to PAR. Shaded regions near small gaps result in similar levels of UV and PAR. Sunlit regions near large or small gaps typically have greater PAR than UV-B. Increasing stand density corresponds to a decrease in UV-B penetration relative to PAR. Therefore, the highest levels of UV-B occur in the upper portions of dense canopies and in open low-density canopies common to early developmental stages of crops and mature orchards.

It is difficult to underestimate the potential of modern biotechnology for improving human health. We can easily contemplate the development of foods with enhanced nutritional content, new medicines, and vaccines for prevention of infectious diseases. Vaccines are one of the great successes of modern medicine, e.g., worldwide control of poliomyelitis, measles, and smallpox. However, the development and implementation of new vaccines remains prohibitively expensive for economically depressed countries where such measures are needed most. Plant-produced vaccines provide a promising new strategy that combines the innovations in genomics, medicine, and plant biotechnology to create affordable biological products. In the past decade, a growing number of research groups worldwide have studied plant expression and oral delivery of vaccine antigens, some showing very promising potential.

ADVANTAGES AND CHALLENGES OF PLANT VACCINES

For more comprehensive reviews of vaccine antigens produced in plants, please see Refs. 1–4. The development of technology for genetic transformation of plants has provided the opportunity to use agriculture for the production of recombinant proteins. Field production using a stable transgenic line would not require large investments in hardware and culture media, thus making scale-up more economical than fermentation culture. Analysis of the economic potential of different crop plants for production of recombinant proteins[5] provides a basis for comparison and suggests real value in the technology. Moreover, plant systems are much less likely to harbor pathogenic microbes than are mammalian cell or whole animal systems. An attractive possibility with edible plants is the ability to deliver vaccine antigens orally, thus obviating the costly purification process required of injectable vaccines. The delivery of vaccines to mucosal tissues (epithelia that line the gastrointestinal, respiratory, and genitourinary tracts) also has the ability to stimulate secretory IgA at those surfaces, which is rarely observed with injectable vaccines.[6]

The biggest challenge for orally delivered vaccines is the digestive system, whose acidic and proteolytic environment may be too severe for all but the most gut-stable proteins and may require encapsulation of antigens. Furthermore, a robust mucosal vaccine must be readily transported across the epithelium for presentation to the underlying lymphoid tissues. Such transport likely requires special epithelial cell-binding qualities that are not universally present in proteins. Nonetheless, a growing number of candidate vaccine antigens have been shown to be orally active.

PLANT EXPRESSION SYSTEMS

There are two main systems for recombinant protein expression in plants: stable genetic transformation and transient expression. Stable transformation causes integration of foreign DNA into the nuclear or chloroplast chromosomal DNA; these lines can be propagated vegetatively or by seeds and thus can be readily scaled up for protein production. Transient expression uses a plant virus that carries the vaccine gene, which is replicated and expressed during systemic infection of the plant host.[2] Such virus-based expression amplifies gene copy number, often resulting in higher expression than stable transformation. However, the larger foreign genes may be unstable in plant virus systems, which results in deletion of the foreign DNA.

Stable nuclear transformation is often achieved using Agrobacterium tumefaciens, which can efficiently transport DNA into plant cells and cause chromosomal integration resulting in Mendelian inheritance. DNA delivery by the “biolistic” method (microprojectile bombardment) is frequently used for plant hosts that are recalcitrant to Agrobacterium. The biolistic method often causes multiple site integration that may enhance expression, but excessive copies or very high mRNA levels may cause gene silencing.[7]
Stable transformation of the chloroplast genome can yield high levels of recombinant protein⁸ due to the high genome copy number. The chloroplast-derived chloroplasts of tomato fruit can also express foreign proteins. Other advantages of chloroplast transformation include maternal inheritance, which limits the potential for transgene escape by dissemination of pollen, and absence of gene silencing. Many foreign genes have been expressed in transplastomic plants, including the vaccine candidate cholera toxin B subunit (CT-B).⁸ A limitation for this strategy is that some eukaryotic cellular processing events (e.g., glycosylation) may not be obtained in chloroplasts.

Tobacco and potato are frequently used as convenient systems for vaccine expression because transformation and regeneration of plants are readily achieved. If purification of antigen for injectable delivery is the goal, tobacco is an attractive choice because of its high biomass production. However, the use of edible plant tissues permits oral delivery, wherein one may avoid extensive and costly purification procedures. Raw potato has been used for both published human trials in the United States,⁴ but a more palatable system is needed. Tomato is a good alternative and was used to express orally immunogenic respiratory syncytial virus (RSV) fusion (F) protein in fruit. Other fruits, including banana, may be useful if efficient transformation systems can be developed. A study of various economic factors suggests that soybean, alfalfa, and corn are the most efficient systems for recombinant protein expression.⁵ A further important consideration is the need to stringently regulate the production of biologicals in plants, in order to prevent the contamination of human food supplies. Thus, the potential for transgene escape by outcrossing must be carefully studied for any potential production system.

**ANIMAL AND HUMAN STUDIES**

A growing number of vaccine candidates have been expressed in plants and tested in animals, resulting in immune responses after oral delivery.²³ In most cases, there was no challenge with infectious pathogens to determine the efficacy of the immunization, but a few reports describe protection from viral or toxin treatment. In a notable recent study,⁹ a peptide from a rotavirus enterotoxin fused to cholera toxin B subunit (CT-B) was co-expressed in potato with a peptide from an *E. coli* fimbrial adhesin fused to CT-A, resulting in assembly of functional ganglioside-binding complexes. Pups of mice immunized by ingestion of transgenic potatoes were partially protected from challenge with rotavirus. The transmissible gastroenteritis virus envelope spike (S) protein was produced in transgenic corn and fed to piglets, resulting in 50% of virus-challenged animals free of diarrhea.³ These studies show potential for edible vaccines as alternatives to injectable vaccines for animals, but they also indicate the need for further optimization of dosage levels or timing to increase efficacy.

Other potential uses for plant-expressed, orally delivered antigens include therapies using autoantigens. For example, treatments for autoimmune disease could be provided by consumption of autoantigens, such as pro-insulin fused to CT-B expressed in potato and fed to NOD mice.¹⁰ Reduced inflammation of pancreatic islets in the treated mice suggests that cytotoxic T cells that kill islet cells in NOD mice had been restricted by immune tolerance. Immunization for the treatment of cancer is the subject of promising studies, e.g., single-chain antibodies from B-lymphocyte malignancies expressed in plants with viral vectors, yielding protection from a lethal injection of tumor cells in treated mice.¹¹

Only three studies of edible plant vaccines in human subjects have been published,¹²–¹⁴ each using a different antigen. Two vaccines were directed against agents of gastroenteritis (*E. coli* and Norwalk virus), whose protein antigens are considered the most likely to succeed by oral delivery due to their gut stability and mucosal cell–binding capacity. The other vaccine targeted hepatitis B virus, not usually considered an enteric pathogen.

Cholera and enterotoxigenic *E. coli* (ETEC) cause diarrhea by secretion of cholera toxin (CT) and labile toxin (LT), respectively, which target epithelial cells via their B subunits’ ability to bind GM1 gangliosides present on cell surfaces. LT-B expressed in transgenic potatoes produced toxin-protective gut antibody responses after ingestion by mice.⁴ The LT-B potatoes became the first human test for plant vaccines¹² in which subjects ate 100 g of raw LT-B potato slices containing 750 µg LT-B at each of three weekly doses. The production of toxin-neutralizing serum antibodies in 10 of 11 subjects proved that ingestion of transgenic plant material could be used effectively to deliver a vaccine in humans.

Most cases of viral gastroenteritis are caused by rotavirus and Norwalk-like viruses, which are potential targets for oral subunit vaccines owing to the ability of their capsid proteins to assemble virus-like particles (VLP). These recombinant VLP can mimic the structure and cell-binding of the authentic virus particles, are acid-stable, and stimulate serum responses in humans. NVCP expressed in plants formed VLP that were orally immunogenic in mice,⁴ and NVCP potatoes were used in a second clinical trial.¹⁴ The volunteers ate 150 g of...
raw potato containing up to 750 μg NVCP. Although the average antibody levels were less impressive than in the LT-B potato study, 19 of the 20 subjects showed significant immune responses. The main conclusion of this study was that a recombinant plant-derived protein lacking the ganglioside-binding activity of LT-B can stimulate oral immunization in humans.

The currently used vaccine for hepatitis B is recombinant viral surface antigen (HBsAg) purified from transgenic yeast cultures. Plant-derived HBsAg was described in the first report of a plant vaccine[15] and showed VLP that were immunogenic by potato ingestion in mice.[16] HBsAg expressed in transgenic lettuce and delivered to humans by ingestion of 250 g (containing approximately 1 μg antigen) caused production of serum antibodies at protective levels in two of three volunteers.[13] Since the dose was quite low, it is likely that the HBsAg had assembled into VLP structure, which enhanced sampling by M cells of the gut-associated lymphoid tissue.[6] Another clinical trial used transgenic HBsAg potatoes delivered to volunteers who had been vaccinated earlier with the commercial injectable HBsAg, in order to test the boosting effect of ingested antigen. The results were promising and are now being prepared for publication.[17]

CONCLUSION

Studies during the past 10 years have shown faithful expression of many different vaccine antigens in plants, and many of these have stimulated antibody responses when eaten by humans or animals. A few reports showed partial protection from challenge with infectious pathogens, indicating a strong potential for plant vaccine technology. However, low expression of antigens in transgenic plants limits the dose that can be delivered in crude material; thus, improvements in plant expression technology are needed. Because doses must be uniform and concentrated, the plant stock will be processed to yield a stable product, such as dried powder that can be formulated with adjuvants and perhaps encapsulated for passage through the stomach. Production systems must maintain rigorous containment to prevent contamination of food supplies; thus, pollen-mediated gene flow should be limited (e.g., with male-sterile lines or chloroplast expression), and post-harvest processing facilities must be dedicated for pharmaceutical production.

INTRODUCTION

The roles of individual virus-encoded proteins have been established for the key steps of virus life cycles. However, the detailed mechanisms of how viruses cause reduced fitness, quality, and yield are yet to be revealed. A thorough understanding of viral pathogenesis requires that host–virus interactions be understood equally well from the plant side of the interaction. Recent developments in plant genomics promise to provide new insights into the ways that viruses perturb host plants. Broadly defined, genomics includes genome sequencing and subsequent study of genome organization and structure (structural genomics) and gene function (functional genomics). This article discusses the application of functional genomics approaches to study host–virus interactions as well as the exploitation of viruses as useful functional genomics tools to probe plant gene functions.

WHAT IS FUNCTIONAL GENOMICS?

Functional genomics studies use genome-wide, global, and/or high-throughput systems to simultaneously study functions of large numbers of or virtually all genes of an organism. The methodologies rely heavily on computational biology, bioinformatics, and statistics to manage and analyze the enormous data sets that are generated. Viral host genomics encompasses pathogenicity, resistance, and discovery of plant gene functions, and has become possible because of two major factors. First, researchers now have access to the complete genome sequences of many viruses and a few plant species (including rice and Arabidopsis), and extensive sequences are available from crop species like maize, wheat, soybean, and tomato. Second, these sequences enable the development and application of new technologies previously not possible to explore the functions of plant genes.

Important technologies for assessing functions of plant genes that have become available recently include DNA microarrays and reverse genetics tools such as insertional mutagenesis (e.g., T-DNA tagging), RNA-induced gene silencing, and virus-induced gene silencing (VIGS).[1] DNA microarrays consist of DNA sequences that are most commonly spotted onto glass slides or synthesized directly onto a silicon or glass substrate. [2] All genes of an organism can be represented on one or a few microarrays, which allows the expression of all genes to be studied in parallel in response to a given condition. Reverse genetics tools, which will be described later in more detail, involve the disruption of genes followed by examination of the effects of loss of gene function on the organism. This suite of technologies allows systematic studies that first associate genes with a plant process and then subsequently determine their roles in that process by observing the mutant phenotype.

FUNCTIONAL GENOMICS APPROACHES TO UNDERSTAND VIRAL PATHOGENICITY

Although viruses are simple entities, interactions with their hosts are relatively complex. Viruses and plants engage in a variety of offensive, defensive, and counter-defensive interactions that ultimately determine the level of colonization. [3] Some specific examples of modifications that plant viruses make in their hosts include gating of plasmodesmata by movement proteins and suppression of RNA interference (RNAi) triggered by replication of viral genomes.[4,5] Viruses also elicit significant changes in patterns of host gene expression—which is expected to influence plant susceptibility and symptom development—and may be a direct result of activities such as gating of plasmodesmata, suppression of RNAi, or interference with other processes. [6]

Recent studies employing genomics approaches have documented changes in the expression of many host genes in response to diverse viruses and viroids. Whitham et al. [7] used Arabidopsis GeneChip [8] microarrays to assay the expression of about 8300 genes over a five-day infection time course in the susceptible Arabidopsis plants. The viruses were ORMV (oilseed rape tobamovirus), TVCV (turnip vein clearing tobamovirus), CMV (cucumber mosaic virus), PVX (potato virus X), and TuMV (turnip mosaic potyvirus). At least 114 genes were induced more than twofold in response to five viruses at one or more time points over the time course. The results demonstrated that diverse viruses induce the expression of common sets of host genes in inoculated leaves, as has been observed in a pea cotyledon system. [8] Further
analysis of the expression of these 114 genes placed them into seven clusters based on their expression profiles. One interesting cluster was composed of only heat shock genes: HSP70, HSP83 (similar to HSP90), HSP17.6, HSP17.4, and HSP23.6. These heat shock proteins shared the characteristic of being induced by ORMV and TVCV (both tobamoviruses) at one day after inoculation, although they were not induced by the other viruses until later times. This result suggests that tobamoviruses might specifically induce HSP expression early. Another interesting cluster of genes was composed largely of plant defense-related genes. In general, the viruses induced the expression of defense-related genes beginning at 2 days after infection. The differential expression of heat shock and defense-related genes indicates that distinct signaling pathways are modulated in response to viruses in susceptible interactions.

Potato spindle tuber viroid (PSTVd) was shown to elicit a variety of changes in tomato gene expression, some of which occur also in tobacco mosaic virus infection in the same host.[10] Unlike viruses, viroids do not encode proteins. Therefore, the RNA genome of viroids is sufficient to cause symptoms in susceptible plants and elicit changes in host gene expression.

Table 1 lists the functional classes of plant genes induced in response to RNA viruses and viroids in the two studies cited above.[7,9] Direct comparisons of the genes induced in the experiments involving viruses and viroids should be made with caution because the nature of the pathogens, time courses, and experimental methodologies were different. Nevertheless, it is intriguing to point out the induction of stresslike responses observed in both studies. For instance, approximately one-third of the genes induced by PSTVd in tomato and by various viruses in Arabidopsis plants are associated with known defense and stress responses. These include genes functionally associated with oxidative stress, heat stress, pathogen stress, defense responses, and transcription factors involved in defense and stress responses. From the Arabidopsis study, it is clear that these sets of genes are expressed differentially over time, suggesting that a variety of host-signaling pathways is modulated as infections proceed. Furthermore, the ability of diverse viruses and viroids to elicit these changes suggests that a conserved feature of virus–host interactions triggers them. At this time, the mechanisms responsible for these gene expression changes are uncharacterized, and their significance remains to be determined. Reverse genetics approaches will be valuable for addressing these issues.

**VIRUS-BASED TECHNOLOGY FOR DISCOVERY OF PLANT GENE FUNCTION**

Virus-induced gene silencing (VIGS) is being exploited to study the functions of plant genes in disease resistance pathways, development, and other processes.[11] VIGS is a form of posttranscriptional gene silencing (PTGS) that utilizes viruses engineered to carry sequences from plant genes to disrupt the expression of the cognate plant genes. VIGS is based on the principle that viruses are targeted by PTGS leading to degradation of their RNA. Once PTGS is induced against a specific sequence, it can degrade that sequence from any source, such as a virus in the cytoplasm or a plant mRNA encoded by a nuclear gene. Thus, the engineered VIGS virus will trigger degradation of itself, the foreign plant sequence it carries, and the corresponding mRNA from the endogenous plant gene. These events lead to a loss of function of the plant gene. The plasticity of viral genomes allows them to accommodate virtually any sequence, enabling most plant genes to be disrupted. VIGS is particularly advantageous for plant species that are not easily transformable (most crops) or not genetically tractable, because of the potential to rapidly generate mutations to facilitate functional analysis of a gene by virtue of a virus infection.

VIGS vectors derived from potato virus X and tobacco rattle virus have been most widely used in dicot species such as Nicotiana benthamiana; tobacco, and tomato; many other viruses hold promise for similar applications in other species.[1] Recently, a VIGS vector was developed from barley stripe mosaic virus, demonstrating the utility of this approach in monocots.[10] VIGS is not only useful in the study of individual genes, but is also adaptable to high-throughput genomics-scale experiments, as illustrated in Fig. 1. The first step in the process is to create a library of plant copy DNA (cDNA) clones by extracting mRNA from plant cells and converting mRNA to cDNA with the enzyme reverse transcriptase. These cDNA sequences are then cloned into the VIGS vector to
create a VIGS library. The libraries can be arrayed so that it is possible to preserve each clone, determine its sequence, and return to it for further analyses. In this example, individual clones are used to inoculate plants to silence the corresponding plant gene and subsequently screen for changes in phenotype. Alternatively, VIGS can be used to systematically study the effects of disrupting selected genes, as illustrated in Fig. 1.

CONCLUSION

Genomics technologies such as DNA microarrays are just beginning to be applied to plant–virus interactions. From initial published report it appears, not surprisingly, that plants are stressed in a variety of ways as viruses invade susceptible hosts. As microarray data are accumulated for both pathogenic and resistant interactions, it will be interesting to compare and contrast the signaling pathways modulated during pathogenesis and resistance. The availability of full genome microarrays will further illuminate ways that viruses perturb the expression of host genes. Reverse genetics tools such as T-DNA insertion lines, RNA-induced gene silencing/RNAi, and VIGS will enable researchers to discover the significance of these gene expression changes and identify genetic components of the signaling pathways involved in regulating the changes. Such integrated studies are expected to reveal mechanisms associated with pathogenesis, onset of disease, and resistance.

On the flip side of the coin, viruses are themselves serving as useful tools for genomics research. Newly developed VIGS vectors include features such as the Gateway™ cloning site, which allows genes and libraries to...
be shuttled in and out of VIGS vectors. Such systems are expected to enable the production of complete VIGS libraries from which an investigator can order the VIGS clone corresponding to any gene of interest.\textsuperscript{[1]} Comprehensive VIGS libraries will facilitate rapid assessment of a gene’s function once it has been associated with a plant trait or response such as viral pathogenesis or resistance.

**REFERENCES**

INTRODUCTION

Plant viruses and viroids cause significant direct or indirect economic losses. Specific losses attributed to certain viruses have been tabulated and reviewed. Early detection of the causal viruses and accurate diagnosis of disease are important in preventing or minimizing such losses. Current methods for detecting viruses and viroids are classified into serological assays, nucleic acid-based techniques, bioassays, and electron microscopy. Generally, the choice of detection method depends on the causal agent (indicated by the symptoms on the plant), the kind and number of samples, the availability of reagents and/or equipment, the time frame available for testing, and the cost. This article discusses some of the techniques used in detecting viruses and viroids, and their applicability in routine testing of plants.

SEROLOGICAL ASSAYS

Serological techniques for detecting plant viruses involve the use of either polyclonal or monoclonal antibodies raised to detect specific viruses. The serological methods that have been applied in the detection of plant viruses include enzyme-linked immunosorbent assay (ELISA), rapid immunofilter paper assay (RIPA) (also known as lateral flow assay), dot immunoblot assay (DIBA), tissue-blot immunoassay (TIBA), and immunosorbent electron microscopy (ISEM).

ELISA—In direct ELISA, the virus is immobilized by either an uncoated or antibody-coated solid phase (usually a polystyrene wall). The immobilized virus is recognized by an enzyme-labeled antibody, and the reaction is visualized by the addition of an enzyme substrate. In indirect ELISA, the virus is reacted with an unconjugated specific antibody, which is in turn detected by an enzyme-labeled anti-immunoglobulin antibody or antibody fragments. The resulting complex is visualized by the addition of an enzyme substrate. Since its introduction into plant viral diagnosis less than thirty years ago, ELISA has been widely used in routine testing of plants because of its relative sensitivity, cost-effectiveness, and ease of use.

RIPA—An increasingly popular technique for detecting plant viruses is based on RIPA. In the commercially available format of RIPA (known as lateral flow, strip, or stick test), a virus-specific antibody is immobilized on the capture line near the top of a membrane strip. A mixture consisting of the tracer virus-specific antibody conjugated to either dyed latex or colloidal metal is applied to a defined region (conjugate pad) just above the lower end of the strip. When the sample (sap) is applied at the lower end of the strip, the virus moves by capillary action through the conjugate pad forming a labeled antibody-virion complex. The moving virion complex is trapped by the immobilized antibody on the capture line and the capture line develops a positive color reaction. In addition to being a rapid test (results occur within minutes), its design makes it suitable for on-site (greenhouse or field) use. Additionally, the sensitivity of RIPA is similar to that of ELISA. The use of RIPA for detecting viruses is limited, however, by the availability of tests in the commercially available format. To date, only 18 specific virus tests are offered in such a format (e.g., ImmunoStrips, Agdia, Inc; Spot Check LF™, Adgen, Ltd, UK).

DIBA and TIBA—These virus detection methods involve spotting plant sap (DIBA) or blotting freshly cut tissue (TIBA) on a membrane that is probed directly or indirectly with a virus-specific antibody. The addition of a suitable substrate results in a positive color reaction. Whereas these techniques may be ideal for routine testing because of their suitability for processing a large number of samples on site, they may not be very reliable due to background (false positives) in certain antibody-host combinations.

ISEM—Another serological detection method involves electron microscopy. The virus is visualized by electron microscopy using leaf dips or purified viral preparations on carbon-stabilized, polyvinyl formal-coated grids pretreated with a specific antibody. This technique is suitable for high titer viruses, but is limited by the uneven distribution of the virus in the plant. Furthermore, because ISEM requires sophisticated equipment, its application in commercial virus testing has been very limited.

NUCLEIC ACID–BASED TECHNIQUES

Techniques have been designed to detect viruses and viroids based on their genome. Double-stranded (ds) RNA...
analysis, hybridization, and amplification reaction-based assays are some of the nucleic acid–based techniques used in routine virus and viroid testing. The choice of these assays is usually dictated by the need for significantly increased sensitivity and versatility, or the lack of a suitable serological test.

**dsRNA Analysis**—As a broad-spectrum assay for detecting RNA viruses, dsRNA analysis entails the electrophoresis of dsRNA isolated from infected plants and its visualization on the gel by ethidium bromide staining. The resulting dsRNA pattern suggests the causal viral group; the identity of the virus can be confirmed by cloning and sequencing. Although the assay is not ideal for large volumes of samples, it offers advantages because it does not require the use of antibodies, sequence information, or probes.

**Hybridization**—In hybridization, the viral nucleic acid is detected by annealing it with a complementary strand of either RNA or DNA, referred to as the probe. The labeled probe allows visualization of the formed hybrid by autoradiography, fluorescence, or enzymatic reaction. Samples may be in the form of membrane-spotted sap or enriched preparations in dot blot hybridization (e.g., viroids) or membrane-squashed tissue in squash blot hybridization (e.g., geminiviruses). A large number of samples can be tested simultaneously by these assays due to simple sample processing. Alternatively, DNA or RNA may be separated on a gel by electrophoresis and transferred to a membrane for Southern or Northern blot hybridization, respectively.

**Amplification**—Offering significantly enhanced sensitivities are amplification-based tests such as polymerase chain reaction (PCR) and nucleic acid sequence-based amplification (NASBATM). PCR is the amplification of a segment of DNA bound by two regions of known sequence. The process involves numerous (25–40) cycles of denaturation of the target DNA, annealing of primers (oligonucleotides that are complementary to the regions bordering the sequence), and primer extension by Taq polymerase or similar heat-resistant polymerases. In the case of RNA viruses, PCR is preceded by the synthesis of cDNA by reverse transcription (RT). In the isothermal amplification method, NASBA™, cDNA synthesis is carried out using a primer containing a T7 RNA polymerase promoter. The RNA in the cDNA:RNA hybrid is digested, allowing the synthesis of a dsDNA using a second primer. With the resulting dsDNA as template, T7 RNA polymerase transcribes amplicons to form multiple copies of antisense RNA, which are used as templates for more cycles of amplification. Amplicons resulting from both PCR and NASBA™ are routinely electrophoresed on gels and visualized either by ethidium bromide staining or hybridization upon transfer to a membrane. In addition, amplicons may be cloned and sequenced.

Aside from their marked sensitivity, both PCR and NASBA™ can be designed to be strain-, species-, or group-specific tests. RT-PCR has been particularly useful in detecting numerous viruses of herbaceous and woody plants, whereas NASBA™ has been used effectively to detect the various strains of PVY. Despite the advantages offered by amplification-based tests, their applicability in routine testing and high throughput analyses is limited by laborious and expensive pre- and post-amplification manipulations. Methods to simplify sample processing (e.g., direct binding or immunocapture of virions) have been evaluated. Detection of RT-PCR-derived amplicons has been simplified by sandwich hybridization in enzyme-linked-oligosorbent-assay (ELISA) in the case of PVY. ELOSA involves a capture probe covalently linked to the wall of a microtiter well and a 3'-biotinylated-specific detection probe, both of which hybridize to resulting amplicons. The formed hybrid is reacted with a strepavidin-enzyme conjugate that results in a color reaction when given the appropriate substrate. Alternatively, amplicons derived by either PCR or NASBA™ may be specifically detected and quantitated in real time using a probe labeled with fluorescent and quencher dyes at either end (e.g., TaqMan and molecular beacons). When the labeled probe binds the amplicon, a sequence-specific fluorescent signal is released in real time with intensity increasing proportionally.

**BIOASSAYS AND ELECTRON MICROSCOPY**

When serological and nucleic acid-based techniques are unavailable, alternative detection methods include bioassays and electron microscopy. Bioassays entail the grafting or inoculation of certain woody and herbaceous plant species (indicator plants) with cuttings or sap from the infected plant materials. The indicator plants exhibit symptoms characteristic of certain host-virus systems within days or months. In electron microscopy, ultrathin tissue slices or plant sap are examined for viral morphology and cytopathology. Based on these observations, the group to which the causal virus belongs is identified.

**CONCLUSION**

Increased sensitivity combined with simplified and inexpensive assays should be the goal in developing tests for effective viral detection and diagnosis. These characteristics should extend the applicability of such tests in routine testing of high volumes of samples. Currently, serological lateral flow assays offer the simplest test format, whereas amplification-based tests prove to be the most sensitive. An assay with both of these properties was
developed to detect a human pathogen in water. The specific detection assay involved solid phase–based extraction coupled with RT–PCR, and amplicon detection by hybridization in a lateral flow format.[13] The development of a similar assay for detecting plant viruses and viroids will be a practical and effective tool for disease management.

INTRODUCTION

The profusion of genome sequences and expressed sequence tags (ESTs) has revealed the existence of a large number of novel genes whose sequences provide few clues as to their specific functions. Therefore, techniques that aid in the quick study of functions of these genes have significant practical value in the post-genomic era. From this perspective, virus-induced gene silencing (VIGS) and RNA interference (RNAi) techniques are promising, as they enable the researcher to link a gene to its function reliably and quickly by silencing its activity.

WHAT IS VIGS?

VIGS was first observed when plants infected with an engineered virus vector carrying host gene sequences showed suppression of the activity of the corresponding endogenous gene.[1] This inhibition of the gene activity was due to a posttranscriptional gene silencing (PTGS) mechanism similar to co-suppression in plants, quelling in fungi, and RNAi in animals. All these related processes involve sequence specific degradation of RNA via highly conserved cellular machinery.[2]

PTGS is currently understood as a form of defense that plants employ to protect themselves from invading foreign nucleic acids such as transposons and viruses, and it is targeted against double-stranded RNA (dsRNA). Most plant viruses make dsRNA intermediates during their replication. The defense machinery of the plant is able to sense the presence of viral dsRNA and cleave it into small RNA (siRNA) by the nuclease activity of enzymes such as DICER.[2] siRNAs help in the priming and amplification of the silencing signal, which then spreads systemically in the whole plant. When a recombinant virus harboring any plant gene sequence is used to infect a host, the dsRNA formed will be homologous to the transcripts from the target gene. Destruction of this dsRNA by PTGS and the formation of the siRNAs will eventually result in the systemic silencing of the target gene’s expression. The phenotype of the plant silenced for a particular gene by VIGS mimics its loss-of-function mutant phenotype. Silencing of phytoene desaturase (PDS) gene using a TRV-based VIGS vector is shown in Fig. 1. The photo-bleaching effect seen is comparable to mutant PDS.

VIGS VECTOR

Several plant viruses have been used to develop VIGS vectors. VIGS vectors derived from tobacco mosaic virus (TMV), potato virus X (PVX), tomato golden mosaic virus (TGMV), and tobacco rattle virus (TRV) have shown varying degrees of success to silence genes in Nicotiana benthamiana, which is a very good host for most plant viruses. When choosing a virus to develop a VIGS vector, several factors need to be considered. Ideally, the virus should spread uniformly and rapidly throughout the plant, including the meristematic regions of the plant, without producing infection symptoms. Viruses that encode strong silencing suppressors such as HC-Pro in potyviruses or protein 2b in cucumber mosaic virus are undesirable to use as VIGS vectors.

The TRV-based vectors have several advantages over other virus vectors, as TRV-based vectors do not induce chlorotic or necrotic symptoms on plants, which are typical to virus infections. This makes the identification of the VIGS-induced phenotype much easier. In addition, TRV invades every cell of the plant and thereby induces uniform silencing.[3,4] PVX and TMV are unable to reach the meristematic or growing regions of a plant, but TRV and TGMV can induce silencing of genes in the meristems and flowers.[3,5]

TRV is a bipartite positive sense RNA virus. RNA-1 encodes the replicase and the movement protein and thus can multiply and spread in the absence of RNA2 (Fig. 2). The TRV-based VIGS vector has the cDNA clones of RNA1 and RNA2 inserted into a T-DNA expression cassette. The multiple cloning sites (MCS) created in RNA2 allow the cloning of target gene sequences for VIGS.[3,4] When Agrobacterium tumefaciens bacterial cultures containing TRV RNA1 and RNA2 constructs are mixed and infiltrated onto the leaves of N. benthamiana, viral RNA is
synthesized. These RNA transcripts then serve as templates for the further replication of viral RNA by the RNA-dependent RNA polymerase encoded by RNA1. Systemic infection by the recombinant TRV then brings about VIGS of the targeted plant host sequences.

**VIGS AS A FUNCTIONAL GENOMICS TOOL**

Several techniques are available to study gene function in plants including T-DNA and transposon-based insertion mutagenesis.[6,7] These methods have limitations such as gene target bias and difficulty in disrupting or tagging all genes. In addition, the high degree of gene duplication in plant gene families often results in insertion or deletion mutants of a single gene lacking an observable phenotype. Finally, lethal mutations in the above approaches are almost always lost. Recently, a single-stranded self-complementary (hairpin) RNA was successfully employed to suppress gene function.[8] All of these approaches, however, rely on the generation of transgenic lines, which is time consuming and even challenging in many economically important plants.

VIGS is a more desirable approach to study gene function.[9] It enables a specific gene to be silenced if its sequence is known. Moreover, it is conditional; hence, loss of mutations due to organismal lethality is less likely

to occur. It is also an excellent system to study gene function in plants that are recalcitrant to Agrobacterium-mediated transformation. VIGS is fast, reliable, and specific. Once a VIGS vector is assembled, any host gene and its close sequence homologues could be efficiently silenced in 2–3 weeks to study its biological function.

**VIGS APPLICATION**

The VIGS has been successfully used in plants to knock out both endogenous genes and transgenes. VIGS of different components of the signaling pathways in flowering, disease resistance, and cell proliferation has helped in the identification of key factors. For example, suppression of the signaling proteins EDS1, NPR1, Rar1, and Sgt1 and of the COP9 signalosome by VIGS compromised the function of the TMV resistance gene \(N\) and showed that these proteins are essential for the resistance mechanism to operate.\(^4,10,11\)

**HERITABLE VIGS**

One of the main disadvantages of the VIGS approach is that the phenotype observed cannot be transmitted to the next generation. Because of this, it is not possible to perform genetic crosses, suppressor or enhancer screens, and other genetic manipulations based on transmissible phenotypes. However, transgenic expression of a replicating PVX (termed PVX amplicon), containing plant exon sequences, consistently induces the silencing of the corresponding endogenous gene in subsequent generations.\(^12\) Therefore, the generation of transgenic lines containing a VIGS vector-based amplicon will provide an invaluable resource for further genetic analyses.

**CONCLUSION**

Even though VIGS has been used successfully to study gene function in plants, it has not been applied in systematic studies at the whole-genome level. Two impressive studies in nematodes utilized the RNAi approach successfully to investigate loss-of-function phenotypes of all the predicted genes on chromosomes I and III.\(^13,14\) Therefore, in future, we need to develop VIGS vectors that could be used to silence genes *en masse* in fully sequenced genomes, such as those of *A. thaliana* and rice. The VIGS approach, in conjunction with the available collection of insertion mutants, will help us to understand the function and interplay of genes that control plant growth, development, and responses to the environment.

**ACKNOWLEDGMENTS**

INTRODUCTION

Plant viruses cause the greatest damage to their host and maximize their potential for spread to uninfected hosts through movement from the initially infected cell. Virus systemic movement in plants is a multistep process, consisting of local spread from the initially infected cell (i.e., cell-to-cell movement) and later vascular-mediated spread to all plant tissues (i.e., vascular-dependent movement). Early studies detected virus spread through the appearance of a visual symptom, followed by biological assay to confirm virus presence. Later, the ability to detect virus components in sampled tissue using antibodies and microscopy enhanced the visualization of virus movement at the cellular level. More recently, the availability of confocal microscopes and fluorescent reporter genes expressed from cloned viral sequences has allowed near real-time observation of virus movement in living cells. Combining these resources with molecular and genetic techniques, viral and host factors involved in virus movement have been identified. Results from recent studies support the dictum that the lack of virus accumulation in systemic tissue is due to one of two causes—either the lack of a virus or host factor necessary for virus movement or the lack of a virus or host factor necessary to defeat or support host defenses. With further advances in methods to visualize virus movement in real time, to harvest and analyze the content of specific host cells, and to manipulate host and viral gene expression, scientists will be able to fully understand how viruses move in plants.

METHODS TO ANALYZE VIRUS ACCUMULATION AND MOVEMENT

A still useful method to estimate the rate of virus movement from an inoculated leaf to the remainder of the plant is by detachment of the inoculated leaf at various times postinoculation. Virus exit from the inoculated leaf is assumed by the appearance of visual symptoms in the remainder of the plant. Steam girdling, wherein phloem tissue in the vasculature is killed by heat treatment, is also used to study virus movement in specific vascular tissue (i.e., through phloem versus xylem tissue). For both leaf detachment and steam girdling studies, the presence of virus in the symptomatic tissue can be verified by inoculation of extracts from putatively infected tissue onto hosts known to yield visible lesions after virus infection (i.e., indicator hosts; see Fig. 1A). Indicator hosts are also useful for estimating the rate of cell-to-cell virus spread by observing the expansion of the visible lesion. Virus movement is now determined more precisely through detection of virus-expressed proteins with microscopy. Initially, virus movement at the cell level was determined using fixed and wax- or plastic-embedded tissue probed with antibodies specific to a virus protein (e.g., Fig. 1B and C). Newer techniques take advantage of our ability to insert and express reporter genes from cloned virus genomes. The use of genes whose protein products fluoresce (e.g., green fluorescent protein (GFP)) allows the monitoring of virus movement in near real time within living cells (i.e., a signal appearing approximately one hour after synthesis of GFP) (Fig. 2).
is now given to the exciting prospect that cell-to-cell movement of some viruses may be coupled to the existence of virus accumulation complexes at the PD (Fig. 1D). [5]

Only recently have host genes been identified that are necessary for the cell-to-cell spread of viruses. [3,6] One recent example is the identification of a host protein that interacts directly with a viral protein necessary for virus cell-to-cell movement. [7] The host protein also interacts with a host enzyme thought to affect PD size and virus movement through its ability to alter callose deposition. Thus the host protein is proposed as an intermediary between a virus movement protein and a host enzyme considered important for PD-dependent virus movement.

**VASCULAR-DEPENDENT ACCUMULATION OF VIRUS**

The vasculature in plants is complicated tissue, regulated in its deposition and composed of many cells with unique structures, implying unique functions for each cell (Fig. 1A–D). [1] Within leaves, vascular tissue is often divided into two groups—minor and major veins—based on their structure and function (Fig. 1A and B, Fig. 2). Minor veins are sites of photoassimilate loading in mature leaves, whereas major veins are sites for the transport and release of photoassimilate in, respectively, mature and developing tissues. Using clones of viruses modified to express GFP, it was determined that both minor and major veins in mature leaves function as initial sites for vascular spread from nonvascular cells. [8,9] In addition, exit and accumulation of virus from developing leaves is from major veins only (Fig. 2). [3,8,9] with some exceptions. [10,11]

Virus transport through vascular tissue is either cell-to-cell via PD, or vascular via sieve tube pores, depending on the location of the virus within the tissue (Fig. 1D). Movement between the various cell types (e.g., bundle sheath cells to vascular parenchyma cells, etc.) may require viral and host factors different from those required for
movement between nonvascular cells (e.g., mesophyll cells to mesophyll cells). Many viral proteins are necessary for vascular-dependent accumulation. Some of these proteins, however, are also known to defeat a host defense response (discussed later). Further work is needed to determine the relationship between vascular transport and host defense suppression functions for all viral proteins required for the systemic accumulation of viruses in plants. Very few host loci have been identified whose function is required solely for vascular-dependent virus accumulation.

HOST DEFENSIVE AND VIRUS COUNTER-DEFENSIVE MEASURES DURING VIRUS MOVEMENT

The preceding discussions highlight how viral and host factors actively support virus movement throughout a plant. Virus accumulation in systemic tissue also may be affected by the ability of the host to prevent virus accumulation and the ability of the virus to defeat the host defense. Such a host-defense/virus–counter-defense system can yield a vascular-dependent virus accumulation pattern similar to that displayed when factors actively supporting virus movement interact. Some host genes have been identified that prevent vascular-dependent accumulation of virus, but allow its cell-to-cell movement. Viral genes that combat the effects of these genes have not been identified. However, the concept of host defensive and virus counter-defensive genes has been more fully developed through the identification of a host enzyme pathway that identifies, targets, and destroys aberrant or overexpressed RNA, including plant virus RNA. RNA silencing is the term for this surveillance system. Recently it was determined that viral proteins, called suppressors, can defeat the surveillance system through multiple ways. Many of the viral proteins that function to defeat RNA silencing were previously shown to support the vascular-dependent accumulation of particular viruses. Thus, in order to understand virus movement it is important to realize that the accumulation of virus in systemic tissue can be influenced by the ability of the virus to interact with host factors necessary for movement and the ability of the virus to avoid host defense factors.

CONCLUSION

Initial studies of virus movement identified strains of viruses with altered movement abilities and loci in plants that controlled movement. In the last 15 years, our understanding of virus movement has increased dramatically due to our ability to clone and alter virus genes and then express these genes alone, as a transgene, or from an infectious virus in plants. Reporter genes such as GFP have aided the analyses of virus spread by allowing near real-time imaging of virus accumulation patterns. Using these technical breakthroughs, researchers have determined rates and routes of virus movement. Systemic accumulation of virus is a balancing act between the expression of viral and host factors that actively support virus movement and those that defend the host or virus from deleterious effects. There will be continued research directed toward identifying viral, and especially host, factors that support or prevent virus accumulation in systemic tissue. However, the next major step in understanding virus movement will be to understand how these factors interact within single cells and at each cellular interphase to control this phenomenon.

Viruses and Viroids: Evolution

Marilyn J. Roossinck
The Samuel Roberts Noble Foundation, Ardmore, Oklahoma, U.S.A.

INTRODUCTION

Viruses and viroids are genetically the simplest of biological entities and are obligate intracellular parasites. They typically have evolutionary rates that are several orders of magnitude greater than those of their hosts. The significance of this rapid evolution is that resistance to viruses, both engineered and naturally occurring, is often short-lived in field crops. On the other hand, this rapid evolution has allowed plant viruses to be used as model systems for the study of molecular mechanisms of evolution. Unlike the evolution of their hosts, which is often measured in millions of years, virus evolution can be measured in as little as 2 weeks. This article will discuss recent studies on the evolution of plant viruses and viroids that have important implications for crop sciences and will explore the current theories about the possible origins of viruses and viroids.

RNA VIRUSES AS QUASISPECIES

The majority of plant viruses are single-stranded RNA viruses. These viruses encode RNA-dependent RNA polymerases that are generally thought to be much more error-prone than the enzymes involved in DNA replication. Error rates for plant viruses have not been measured directly, but for animal RNA viruses, they are about 1 in $10^4$ nucleotides copied. Combined with the short generation times of RNA viruses, this can lead to highly diverse populations within a single host, known as quasispecies. However, the level of genetic diversity in individual quasispecies varies among closely related viruses and among hosts infected with the same virus. In addition, not all RNA viruses generate detectable levels of variation in their populations. This indicates that quasispecies population structure is more complex than the simple accumulation of mutations, but factors that control virus population diversity are still unknown.

The practical implication of a highly diverse quasispecies structure is that the virus will most likely be more adaptable to new environmental challenges, such as breeding for resistance or engineered resistance, because more fit variants may already be present in the population. The level of diversity has been correlated to the size of the host range. High levels of diversity could also account for the rapid emergence of introduced viruses in crops.

ORIGIN OF PLANT VIRUSES

The numerous RNA viruses of plants can be divided into a small number of superfamilies and taxonomic families based on the structure of the genome and nucleotide sequence identity. Some superfamilies, such as the alphavirus family, have species that infect plants and others that infect animals. It is likely that these viruses have a common ancestral origin, possibly an insect virus. The plant viruses in the Bunyaviridae family, as well as several other plant virus taxa, replicate in both their plant host and their insect vector, and at least in some cases, the adaptation of the virus seems more closely directed by the insect than the plant. Other plant virus families, such as the Potyviridae, contain only members that infect plants.

Plant viruses have different requirements for systemic infection than animal viruses because they must be able to move between cells with cell walls. Hence the viruses contain specific genes encoding movement proteins that enable the virus to move from cell to cell. It seems likely that these genes were originally acquired from the plant host because plants encode proteins that act in a very similar manner.

Most plants also contain very low titer viruses known as cryptic viruses. These are double-stranded RNA viruses that are unable to move from cell to cell and only replicate poorly. They are disseminated through cell division and by seed or pollen transmission. These viruses may represent precursors to plant viruses that have not yet acquired movement proteins. One possible source of cryptic viruses is from endophytic fungi, which are very often infected with double-stranded RNA viruses. During the plant-fungal symbiosis, it is possible that on rare occasions, some virus escapes into the plant cells, where it can replicate, albeit poorly, but has no mechanism to move. This theory is supported by the similarity in the RNA-dependent RNA polymerase between Beet cryptic virus and the fungal virus Discella destructiva virus (unpublished data) and by the observation that Brome mosaic virus, with some manipulation, can replicate in yeast cells.
When phylogenetic analyses are performed with individual genes of RNA viruses, the trees are often incongruent, indicating separate evolutionary histories for different genes. This strongly supports a modular evolution theory for viruses, although there are also different host constraints on different genes that may also influence their evolution. The most conserved regions are three domains in the proteins that make up the viral components of the replicase: methyl transferase, helicase, and polymerase (Fig. 1). The movement proteins also exhibit conservation of structure, but little conservation of primary sequence, and hence it is not clear if they are similar as a result of divergent or convergent evolution. If they are indeed derived from plant genes, it is possible that they have a common root that is much deeper than that of the replicase genes, and hence the evolutionary history is obscured.

Of the plant DNA viruses, the geminiviruses are among the most economically important. These viruses replicate by making use of the host DNA polymerase, but still manage to establish highly diverse populations when different field isolates are compared. There is extensive evidence of modular evolution in these viruses, similar to what is seen in RNA viruses, with recombination and reassortment common themes in the evolution of both groups.

The origin of the geminiviruses is unclear. Some geminivirus sequences have been found integrated into plant genomes, while other studies have shown that geminiviruses can replicate in Agrobacterium tumefaciens, suggesting a bacterial origin (reviewed in Ref. [6]). Other DNA viruses, most notably some of the pararetroviruses, are not only found integrated in plant genomes, but can also excise and establish episomal infections.[7] While integration does not necessarily indicate a plant origin for the virus, it does suggest a long association between virus and host.

**EVOLUTION AND ORIGIN OF VIROIDS**

Viroids rely on the host RNA polymerases for replication, enzymes that are also much more error-prone than DNA polymerases. Hence viroids also exist as highly diverse populations or quasispecies. A large number of pathogenic viroids have been described and analyzed, but viroid diseases were not described before the 20th century. It is thought that viroids entered crop plants with the advent of worldwide plant movement and monoculture practices in agriculture from wild plant hosts where they were likely nonpathogenic.[8] Viroids contain ribozyme structures that resolve the concatemers generated during replication and hence have been characterized as molecular fossils, representing the earliest forms of life on earth. There is an ongoing debate concerning the monophyletic nature of viroids, but the most recent studies indicate that despite enormous nucleotide sequence diversity, the conservation of structural elements, especially with regard to position in the viroid genomes, does indicate a common ancestor.[9]

**CONCLUSION**

Plant viruses are an increasing threat to crops, and the effectiveness of methods for long-term control is not known. However, while the evolutionary potential of viruses may mean that control measures are ineffectual, the plasticity of viral genomes allows them to be exploited as tools for genetic engineering. Virus expression vectors may be the simplest and most appropriate method for expressing foreign genes in plants.[10] Hence virus evolution can be both a menace and a benefit to crop sciences. Long-term control of viral diseases in plants may include methods for control of viral symptoms, rather than eradication of the virus.

Viruses and Viroids: Evolution

Water Deficits: Development

Kadambot H. M. Siddique
The University of Western Australia, Crawley, Australia

INTRODUCTION

Despite water being the earth’s most abundant compound, water deficit is the single most important factor limiting crop yields worldwide. Of the earth’s water supply, 97% is saline and 2.25% is trapped in ice, leaving only 0.75% available in freshwater aquifers, rivers, and lakes. Agriculture is the major consumer of fresh water worldwide (69%). Increasing demands being placed on both food and water resources throughout the world require that agriculture be more efficient in its water use without sacrificing production. To enable more efficient distribution and utilization of water resources, a greater understanding is required of plant–water relations, in particular the way in which water deficits develop and affect plant growth and productivity.

THE SOIL, PLANT, AND ATMOSPHERE CONTINUUM

The plant-water deficit that develops in any particular situation is the result of a complex combination of soil, plant, and atmospheric factors, all of which interact to control the rate of water absorption and loss. In plants, water deficits develop as a consequence of water loss from the leaf as the stomata open to allow the uptake of CO2 from the atmosphere for photosynthesis. The water lost by transpiration from the leaf mesophyll cells is replaced by water drawn from the soil through the root, stem, and leaf via the xylem. The movement involves both symplastic and apoplastic pathways, i.e., from cell to cell via the symplasm and along the cell walls and xylem vessels, respectively. Both pathways create resistances to flow between the soil and leaf. This pathway of movement is a continuum between the soil, plant, and atmosphere.

It is generally accepted that water moves through the soil–plant–atmosphere continuum along a gradient of decreasing water potential from the soil, through the plant, to the atmosphere. The driving force for the upward movement of water is the negative hydrostatic pressure (tension) that develops in the xylem of transpiring plants. Except for halophytes, the solute content of the xylem sap is usually very low, and thus its solute potential is very close to zero. Water forms a continuous liquid system from the soil up to the evaporating surfaces in the leaf mesophyll. When water evaporates from the leaf cells, the reduction in potential at the evaporating surface (the leaf cell walls) causes movement of water from the xylem to the evaporating surface, which in turn reduces the pressure of water in the xylem and causes the ascent of water. This reduced pressure is transmitted throughout the liquid continuum to the root surfaces, where it reduces the root water potential and causes uptake of water from the soil.

Changing water availability has the greatest effect on the soil–root boundary that forms an interface between the plant and its environment. The difference in water potential between the plant and the soil depends on the evaporative demand, the extent to which the plant can meet that demand, and the water-conducting properties of the soil and plant. It was previously thought that there was no direct relationship between the water potential in the leaf and the water potential in the soil, with the soil–water potential acting only to establish an upper limit of recovery possible by the plant during the night. However, current evidence suggests that plant growth regulators such as abscisic acid (ABA) may play an important role in transferring the message of increasing soil and root water deficits to the shoot.

WATER STATUS OF CROP PLANTS

The water status of a crop plant is usually defined in terms of its water content, water potential, or the components of water potential. The total water potential can be partitioned into components consisting of the osmotic potential, turgor pressure, matric potential, and gravitational potential. In addition to water moving from the soil to the atmosphere, the lower water potential in the leaves and stems results in water moving from the leaf mesophyll cells and the parenchyma cells surrounding the xylem and phloem. This water not only acts as a reservoir of water buffering the plant against diurnal changes in water deficit, but also induces changes in cell volume. Seed growth is the final plant process affected by soil water stress (e.g., in grain legume species the water relations of the embryo are isolated from the water relations of the maternal...
There is a close coupling of pod- to plant-water status, but a clear isolation of seed-from pod-water status. This results in relatively constant seed coat turgor despite changes in the water potential of the maternal plant environment. It is thought this homeostasis may be part of a mechanism to ensure continued seed filling and assimilate redistribution, even when low water potentials have reduced the current availability of assimilates from the leaves.\textsuperscript{[3]}

Plants are in a position to extract water from the soil only when their water potential is lower than that present in the soil. Thus water in the plant is seldom in equilibrium with water in the soil. In fact, water deficits occur in the tissues of all transpiring plants as an inevitable consequence of the flow of water along a pathway in which frictional resistances and gravitational potential have to be overcome.\textsuperscript{[1]} At times during the day, all plants (with the exception of those in humid climates) are undergoing some degree of water deficit. The extent of any imbalance between transpiration and water uptake is limited by the storage capacity of the plant: For crop, forage, and pasture species this is usually less than one-third of daily transpiration.

The difference in water potential between the plant and the soil depends on the rate of uptake of water from the soil and the water-conducting properties of the soil and plant. The progressive changes in soil– and plant–water potential as the soil dries out are presented schematically (Fig. 1).

![Fig. 1 Schematic representation of changes in leaf–water potential (\(\psi_{\text{leaf}}\)), root–water potential (\(\psi_{\text{root}}\)), and soil–water potential (\(\psi_{\text{soil}}\)) as transpiration proceeds during a drying cycle. The same evaporative conditions are considered to prevail each day; the horizontal dashed line indicates the value of \(\psi_{\text{leaf}}\) at which wilting occurs. (From Slatyer, R.O. 1967. Plant–Water Relations, Academic Press, New York.)](image-url)

### EVAPOTRANSPIRATION

Evaporation from plant communities is frequently termed evapotranspiration, to signify the combined soil-plant nature of the evaporating surfaces. The evaporation of water, whether it be from a free water surface, wet soil, or as transpiration from plants, is an energy-dependent process involving a change in state from the liquid to the vapor phase; the rate is a function of the vapor pressure gradient, the resistance to flow, and the ability of the soil and plant to transport water to the sites of evaporation.\textsuperscript{[4]}

The primary source of energy for this process is provided by radiation from the sun. Secondary sources include scattered and reflected radiation from the sky and clouds, as well as sensible heat transferred from the adjacent air, crop, and soil. The transport of water vapor molecules from the wet surfaces to the atmosphere occurs by molecular diffusion and turbulent eddy movement.\textsuperscript{[5]}

### MECHANISMS FOR CONTROL OF WATER TRANSPORT

The relative magnitude of water supply and water loss appears to determine the degree to which plants are water-deficient. However, because plants are living organisms, it is important to realize they do not provide solely a pathway for the movement of water from the soil to the atmosphere. Plants possess mechanisms for osmotic regulation that effectively control the flow of water according to their water status.\textsuperscript{[4]}

The additional resistance encountered when evaporation occurs via plant surfaces is of great ecological importance and greatly affects evapotranspiration. In well hydrated plants, resistance is very small. Thus, the evapotranspiration from a soil completely covered by vegetation well supplied with water is very close to the evaporation from an open water surface and is called potential evaporation. Evapotranspiration from non-stressed crops is largely governed by meteorological conditions in the atmosphere external to the soil-plant system rather than by plant and soil factors. Crop canopy photosynthesis, transpiration, or leaf extension growth usually do not show midday depressions caused by high evaporative demand unless the soil water supply is depleted below a threshold of ca. 50\% of total extractable soil water. The exact point of the threshold water content is difficult to distinguish and is usually extrapolated from measurements taken when evapotranspiration/maximum evaporation is clearly reduced by drought.\textsuperscript{[6]}

The plant, in contrast to the soil, does exercise control over water loss through its stomatal and cuticular resistances in the water pathway and also through its ability to
reduce the radiation load through active and/or passive changes in leaf orientation. Because these controls are located at the leaf surface, the internal water status of the plant is closely coupled to that of the soil and less closely coupled to the atmosphere.\[1\]

Regulation of stomatal conductance enables the plant to reversibly modify gas exchange with the atmosphere, with a time scale of only a few minutes. This short-term regulation may both optimize the dry matter production and offer some protection from xylem embolism or other detrimental effects of very low leaf water potential.\[7\] Stomata do not respond to changes in leaf–water potential or relative water content (RWC) until a critical threshold level of these parameters is reached, and then the stomata close over a narrow range of leaf–water potential or RWC. There is now considerable evidence to support the theory that a chemical message—originating in dehydrating roots and conveyed by the water flux towards the stomatal complex—can control stomatal conductance.\[8\]

Because stomata act as regulators for CO\textsubscript{2} exchange, water deficits sufficient to close stomata must also depress photosynthesis. Photosynthesis declines initially as a result of stomatal closure, but prolonged and severe water stress can lead to depression of chloroplast and enzyme activity and to nonstomatal effects on photosynthesis.\[11\] In shoot tissues, when water deficits limit the supply of CO\textsubscript{2} for photosynthesis, a number of reversible mechanisms down-regulate the efficiency of excitation energy transfer to Photosystem II.\[2\] Dark respiration is depressed whenever the water deficit is sufficiently great to close stomata and decrease photosynthesis, but the decrease in dark respiration is less than that of net photosynthesis.\[11\]

A high cuticular resistance is associated with either thicker cuticles or with cuticles enriched with hydrophobic materials. Although the plant cannot flexibly control this, cuticular resistance has been found to decrease with increasing temperature and atmospheric relative humidity.

**MEASUREMENT OF PLANT–WATER RELATIONS**

Any study of plant–water relations requires accurate methods for measuring them. Indirect methods that have been used to characterize the leaf water status include visible wilting, color change, leaf rolling, leaf temperature, leaf thickness, stomatal conductance, photosynthetic rate, and leaf permeability. Direct measurements can be undertaken using standard equipment such as the pressure chamber, psychrometers, and infrared gas analyzers. These have now been joined by newer technologies, such as the pressure probe, acoustic emission sensors, portable photosynthesis and fluorescence meters with solid-state circuitry, in addition to sophisticated modeling techniques for extrapolation to larger scales.\[2\]

Mass spectrometers can be used to trace source water through the measurement of a combination of stable radioactive carbon isotopes suspended in water, and may also have the potential to reveal the quantitative contribution to atmospheric fluxes of transpirational water derived from vegetation. Other approaches such as mass-balance techniques, micrometeorological methods, and measurement of liquid flow and vapor fluxes can be used as a basis for scaling up to the level of canopies and stands of vegetation.

**EFFECTS OF WATER DEFICITS**

Long-term severe water deficits can have a negative effect on crop growth and yield, and may even result in senescence of the plant. It has been suggested that drought resistance of crops may be improved via breeding for specific phenological, morphological, physiological, or biochemical characteristics that improve yields in water-limited environments. These characteristics include early vigor, transpiration efficiency, stomatal control, abscisic acid accumulation, proline accumulation, osmotic adjustment, carbon remobilization, rapid grain growth, changes in hydraulic conductance, membrane stability, and lethal water potential.\[9\] It is, however, important to note that water deficits do not always lead to detrimental effects on yield. Mild or early water deficits may in fact increase yields or at least have no effect on yield, especially in indeterminate species.

**CONCLUSION**

The global atmospheric CO\textsubscript{2} was in a steady state at a concentration of about 280 \(\mu\text{mol/mol}\) 150 years ago and has been rising steadily since then as a result of human activity. Over the past 20 years, the annual rate of increase has varied, depending on global economics, between 1 and 2 \(\mu\text{mol/mol}\).\[10\] The rise in atmospheric CO\textsubscript{2} concentration is likely to affect global climate and to cause regional changes in air temperature and humidity, length of growing season, precipitation, and evaporation, all of which will affect plant water relations.\[10\] At a plant scale we may expect to see substantial but rather variable increases in plant growth and changes in the phenology of growth processes.

Stomatal conductance has long been known to decrease at high levels of CO\textsubscript{2}. Empirical data suggest that
increases in plant size, particularly in leaf area, may offset any possible advantages to water economy resulting from stomatal closure. There is also evidence to suggest that the growth-enhancing effects of elevated CO2 may to some extent offset the growth-reducing effects of water stress.[10] Changes in land use and regional climate brought about by anthropogenic incursions mean that crop productivity in more marginal rainfall areas will be of increasing importance in world agriculture. Expansion to these areas requires the ability to identify and breed for characteristics that better enable crop plants to cope with limited water availability.

Water Movement Through the Plant

Jonathan Comstock
Boyce Thompson Institute for Plant Research, Ithaca, New York, U.S.A.

INTRODUCTION

Terrestrial plants have tremendous water transport capacities to support photosynthesis in an aerial environment. Because photosynthetic capture of CO₂ begins with gas-phase diffusion between the ambient air and leaf intercellular spaces, there is no selective barrier to allow CO₂ uptake while preventing a proportional water loss (transpiration). Consequently, 95% or more of total plant water uptake is simply lost again to the atmosphere during the photosynthetic process, and plant water requirements for net growth are very high. Support of the transpiration stream requires both an extensive root system for extraction of soil water and also highly specialized long-distance transport tissues (xylem) that maintain a continuous, high-capacity pathway for the flow of water reaching all tissues in the plant body.

COMPARTMENTATION AND TISSUE SPECIALIZATION

The distinction is often made between symplastic and apoplastic water movements in plants. Apoplastic space is defined as external to living cells. Because plant cell walls lie external to the bounding cell membranes, this includes the porosity of cell walls, surface films adhering to them, and all intercellular spaces. Also considered part of the apoplast, but quite distinct in its characteristics, are the highly specialized conduits of the xylem tissues, which form a system of hollow, nonliving capillaries at functional maturity. Symplastic pathways are those within the boundaries of living cell membranes, including cytoplasmic and vacuolar volumes and the interconnections of living cells by plasmodesmata. Movement of water between apoplastic and symplastic compartments is usually determined by gradients in total water potential—a thermodynamic measure influenced, most importantly, by both pressure and osmotic concentration. However, water movement within a single compartment, such as through porous walls or in xylem conduits, is driven primarily by the pressure term alone and not by total water potential.

Long-distance water movement within plants occurs predominantly in the specialized conduits of the xylem—the tracheids and vessels. Tracheids are conduits that develop from a single living cell and are rarely more than a few millimeters in length, whereas vessels are multicellular in development and range from several millimeters to several meters in length. Both tracheids and vessels are dead at functional maturity, have open lumen without cellular contents, and ultimately have sealed ends. The open lumen provides a low-resistance pathway and allows xylem tissues to have six or more orders of magnitude greater conducting capacity for water transport than an unspecialized tissue such as parenchyma in the root cortex or leaf. However, after flowing for a while in a conduit lumen, the sealed ends require that water must move laterally through the overlapping sidewalls in specialized regions of the thin and porous primary wall—referred to as a “pit membrane.” Because of this requirement for lateral passage, whole conduits are not stacked end to end in series but overlap with the next axial component over a substantial fraction of their length.

The tracheid is considered to be monophyletic in origin and is present in most vascular plants. In contrast, the vessel is polyphyletic in origin and is lacking in many important groups of plants. When both conduit types are present, as in most angiosperms, the longer, larger-diameter vessels will usually provide most of the transport capacity. This is because the hydraulic conductance of the lumen of an individual conduit increases with the fourth power of its radius, so xylem tissues with large-diameter conduits can have much higher hydraulic conductance per unit xylem cross-sectional area. However, as tracheid diameter increases, hydraulic conductance may become limited by the tremendous number of pit membrane crossings between the root and the shoot. Xylem with small-diameter tracheids has more total wall surface area for enhancing pit membrane connections, whereas lumen and pit membrane resistances to flow can be kept balanced by an increased conduit length in vessels.¹

Initial absorption of water from the soil must occur radially across the root cortex before entrance into the centrally located root xylem for long-distance transport. The pathway of radial movement can be rather complex—involving a combination of apoplastic and symplastic...
transports across the cortical tissues. Water may move repeatedly from symplastic to apoplastic space during this transit, and the hydraulic conductance of individual cell membranes becomes very important.[2] Cell membranes tend to have rather poor hydraulic conductance, unless they contain specialized proteins (aquaporins) that form pores, allowing the passage of water but not solutes. The density and spatial distribution of aquaporins can be very important in facilitating water movement through living tissues. Similarly, water exiting xylem in the leaf most often moves, at least briefly, through living parenchyma cells.[3]

Quantitatively, most xylem transport end in the extensive network of fine leaf veins, although flowers, fruits, and other organs are all vascularized to some degree. Phloem tissue is also present in this veinial network, collecting photosynthate from the leaves and repackaging many of the mineral nutrients initially traveling in the xylem from the roots. These materials, together with some volume flow of water, are then delivered to all the “sink tissues” of the plant. In a few cases, such as a heavily cutinized fruit with few stomata, sink tissues may actually receive most of their water requirements from phloem transport. Such water has still first traveled from the root to the shoot in xylem, and the necessary hydration volume of such nontranspiring tissues represents a very small part of the total water economy of a plant.

MECHANISMS OF WATER MOVEMENT AND XYLEM FUNCTION

Water movement within the xylem conduits is always down a pressure gradient, but the nature, origin, and maintenance of this pressure gradient can differ dramatically under different circumstances, and sometimes as part of a regular day/night cycle. The pressure throughout the xylem plumbing network may sometimes be positive with respect to the atmosphere, like water in household pipes. Positive xylem pressure arises from a phenomenon called root pressure, and is generally associated with conditions of very low transpirational demand, such as stomatal closure at night or the leafless condition of perennial winter-deciduous plants in the early spring. More often, and especially during periods of high transpiration, the absolute pressure throughout the xylem is negative with respect to atmospheric pressure, like water being pulled through a straw under tension.

Root pressure depends on the ability of the endodermis (a specialized layer of the innermost root cortex with suberized radial walls) to act as an organ-level semipermeable membrane surrounding the central xylem tissues. The endodermis restricts apoplastic exchange between the root xylem and cortical apoplasts, both enabling the capacity for differential uptake of soil solutes into the xylem and creating the potential for osmotic pressures between xylem and cortical tissues. If the xylem is actively loaded with solutes associated with mineral nutrient uptake, an osmotic pressure may build up in the root xylem, which draws in water as well, generating a positive pressure throughout the xylem conduits. Many herbaceous plants in wet soil at night actually excrete water droplets from the ends of minor veins on the edges of leaves—a process referred to as guttation. However, plants do not take up nearly enough solutes such that the large volume of daytime transpiration can be supported primarily by this osmotic mechanism.

The large volumes of water needed to support transpiration move through the xylem primarily under a gradient in tension (pressure below atmospheric) ultimately created by the process of transpiration itself.[4] When water is lost from a leaf through the stomatal pores, the water vapor in the leaf intercellular spaces is replaced by evaporation from the wet cell walls. This creates a water deficit in the cell walls, and water retracts into the micropores of the wall. However, due to its surface tension, water resists assuming the tortuous curves associated with retraction into pores with radii that are only a fraction of a micron. Thus transpiration generates a tension in the apoplastic water bounding the intercellular air spaces. This lowers the water potential of the associated cells and is ultimately transmitted, both through apoplastic and symplastic connections, to the leaf xylem. The tensions first reach the xylem conduits at pit membranes that separate the peripheral conduit lumens from the surrounding bundle sheath parenchyma.[3] Once transmitted into the sap of the conduit lumen, the tension develops into a continuous gradient, pulling water up through the interconnected conduit water columns from the root, and ultimately from the soil. This is facilitated by the very special characteristics of the xylem conduits derived from their sealed ends and the fact that passage of water (or air) in or out of the lumen can only occur through the micropores of the pit membranes. Tension develops in the vessel lumen, but there is little change in water volume because the water adheres strongly to the conduit walls and fills the lumen completely without void or gas spaces. In such a closed capillary, water actually has a substantial tensile strength sustaining tensions of −5.0 MPa or more without undergoing cavitation, or sustaining spontaneous rupture of the water column to allow vapor-filled void spaces. When cavitation does occur, it is generally not from spontaneous failure of water cohesion, but rather from the aspiration of an air bubble entering into the conduit through a pit membrane pore.
The critical tension that can be sustained without failure is determined by the diameter of the pit membrane pores. The xylem conduits themselves must also be heavily reinforced with thick secondary walls to withstand these large forces without collapsing inward. The tensions that can be tolerated in the xylem are highly species-specific, varying several fold depending on wall dimensions and pit membrane morphology.

INTEGRATION OF WATER TRANSPORT AND TRANSPIRATIONAL DEMAND

Plants show an almost surprising consistency in their shoot water potentials during transpiration when they are growing in moist soil. Dynamic water stress, the total pressure drop from the root to the shoot arising from frictional resistance to transport, rarely exceeds 0.5–1.0 MPa. Because plants show tremendous variation in their actual transpiration rates, this means that there must be a strong positive correlation between maximal stomatal opening and hydraulic conductance. This has been demonstrated in both wild and crop species. For the xylem conduits, which are dead at functional maturity, most of this coordination must be achieved during growth. Some plants also appear to fine-tune the hydraulic conductance of their existing xylem by subtle alterations of solute content in the xylem sap, affecting pit membrane permeability. Aquaporins, especially in the root cortex, have also been shown to undergo diurnal fluctuations in synthesis correlated with diurnal fluctuations in the hydraulic conductance of root membranes.

Careful regulation of dynamic water stress is needed because of the danger of cavitation in the xylem. The same tension gradients that are the fundamental driving forces for xylem transport also define the limits to transport without cavitation. When cavitation occurs, almost all water will drain out of the conduit, which loses its ability to transport water, but the closed end walls and the pit membranes serve as check valves, limiting the spread of dysfunction and requiring that cavitation only propagate by independent events, conduit by conduit. Nonetheless, exceeding the limits for sustainable tension could result in a catastrophic collapse of the transport process, and yet plants appear to approach these limits regularly. Cavitation of a limited fraction of the conduits is a common phenomenon. Some herbaceous species even show a regular diurnal pattern of partial cavitation, and use root pressure at night to help refill the conduits. Less well understood are a smaller number of plants that have been shown to be capable of xylem refilling even under conditions where the surrounding xylem is still under tension.

Ultimately, the coordination of hydraulic conductance and maximal transpiration also requires extensive stomatal control and feedback that are sensitive in various forms to the tensions developing in the apoplast. Stomata are the gates through which most water loss occurs, and it is they, and not any of the intervening points of water transport, which can control the actual magnitude of transpiration. They open to allow the entry of CO₂ for photosynthesis, but may exhibit partial closure in response to numerous signals. Dry ambient air, which would cause excessive transpiration, often results in partial stomatal closure to maintain a stable maximum transpiration rate through the day. Water stress experienced by the roots results in hormonal signals released into the transpiration stream itself and modulating stomatal conductance, and evidence exists as well for feedback loops directly between leaf water potential and stomatal behavior. This control, avoiding excessive fluctuation in maximum transpiration and xylem tension, is essential to maintain the integrity of xylem function and stable water transport to the shoot.

CONCLUSION

Most water transport within the plant serve to support the transpiration stream and photosynthetic activity. Long-distance transport from the roots to the foliage occurs in the xylem conduits, which have the somewhat unique property of being dead hollow tubes at functional maturity. Much shorter but equally important pathways for water movement occur in both roots and leaves as water moves through various kinds of living tissues between the soil and the root xylem, and between the leaf xylem and the sites of evaporation. Very active areas of current research include the regulation of membrane properties, especially aquaporin distribution and gating; the limits to xylem function, including the dynamics of cavitation and variation among species in mechanisms of cavitation repair; and the specific signal transduction mechanisms that regulate stomatal aperture and transpiration within the existing limits of the water transport system.

Root Membrane Activities Relevant to Plant–Soil Interactions, p. 1110
Water Deficits, p. 1284

REFERENCES

INTRODUCTION

Less water available for irrigation and the demand for ever-greater productivity from rainfed and irrigated agriculture are major challenges for the 21st century. Agronomic and engineering improvements can help meet these challenges. There are also several plant attributes that have potential to be exploited for greater water use efficiency of crop production. In this overview, plant attributes and agronomic practices that may contribute to greater water use efficiency of rainfed agriculture will be emphasized, although many are also important for irrigated agriculture. Examples will be highlighted from current research with temperate cereals.

AVENUES FOR GREATER WATER USE EFFICIENCY

The term “water use efficiency” has a variety of definitions.[1] In agronomic contexts, most of these definitions describe a ratio of grain yield and some measure of water used or water available for crop growth.[1] Yield formation of rainfed crops grown on a finite supply of water can be described more explicitly as a function of 1) the amount of water used by the crop (ET); 2) the water use efficiency for biomass growth (W); and 3) the harvest index (HI), i.e., how much of the final biomass is partitioned to grain.[2] Closer dissection[3,4] reveals two important avenues for improving crop W: increasing the amount of total water use that is actually transpired by the crop rather than lost as evaporation from the soil surface and improving crop transpiration efficiency (WT), i.e., biomass production per unit water transpired.

MAXIMIZING TRANSPIRATION

Restricting Evaporation from the Soil Surface

Evaporation from the soil surface can account for between 20 and 70% of growing-season water use, varying with how frequently the soil is rewetted and the rate and extent of canopy closure. So, restricting water lost by evaporation from the soil surface can dramatically improve crop W. A reduction in soil evaporation to promote greater transpiration is most easily achieved through the rapid development of leaf area to shade the soil surface from direct solar radiation.[3,4]

Good stand establishment and vigorous early plant growth will both contribute to rapid leaf area development. Good stand establishment is best achieved by plants with vigorous growth of the primary shoot that extends to the soil surface, i.e., either the coleoptile or the hypocotyl. Desirable traits are primary shoots that reach the soil surface more quickly if seed is sown relatively shallow; shoots that reach the soil surface much more consistently if seed is sown deep, such as when farmers are seeding into receding moisture; and shoots that are better able to penetrate crusted topsoils and retained stubble.[4]

Once plants have emerged, traits important for vigorous early leaf area growth may be associated with a larger embryo size, a greater relative growth rate, or a greater investment in leaf area per unit plant growth. Barley, for example, has a much faster rate of early canopy growth than bread wheat due to a larger embryo size and higher specific leaf area. These desirable traits have been combined in a wheat breeding program in Australia to produce new parental lines with early leaf area growth that is double that of current varieties.[5] Soil shading may be further enhanced by more prostrate leaf display.

Agronomic practices such as retention of residues from previous crops can be effective in shading and insulating the soil surface to restrict soil evaporation. Sowing an adequate density of large, healthy seeds at the optimum depth in a well-prepared seedbed will promote good stand establishment. Vigorous leaf area growth can be promoted and sustained by providing adequate levels of major nutrients such as N and P, removing imbalances of minor nutrients and pH, controlling shoot and root diseases, and minimizing soil compaction and waterlogging.

Capturing and Extracting Subsoil Moisture

Water that drains beyond the depth of rooting is lost for dry matter production by the crop. Practices that minimize
drainage in irrigated and rainfed agriculture are important, not just for greater water use efficiency but also for avoiding environmental degradation. Water extracted by the crop from depth will all be used in transpiration, and so extracting available subsoil moisture is important for increasing W.

Management practices and plant attributes that promote vigorous shoot growth will generally also promote vigorous root growth, encouraging water capture. In many rainfed and irrigated cropping systems, there may be constraints, such as waterlogging, compacted soil layers, nutrient or pH imbalance, and root pathogens, that restrict the depth of rooting or water uptake from depth. Growing ‘‘probe’’ genotypes known to be susceptible to or tolerant of a particular condition can be a useful way of identifying a particular subsoil constraint.

**MAXIMIZING TRANSPERSION EFFICIENCY**

At its most basic, W_T may be defined as the ratio of the instantaneous rates of CO_2 assimilation (A) and transpiration (T) at the stomata.[5] These instantaneous rates can be described by relatively simple equations.

\[ A = g_c(c_a - c_i) \quad (1) \]

\[ T = g_w(e_i - e_a) \quad (2) \]

Eqs. 1 and 2 both consist of two components: the stomatal conductance (g) to CO_2 (g_c) or water vapor (g_w) and the concentration gradient of CO_2 (c_a - c_i) or water vapor (e_i - e_a) between the air and inside the leaf.

Leaf-level W_T can be closely approximated by Eq. 3, which combines Eqs. 1 and 2 and in which the factor 0.6 refers to the relative diffusivities of CO_2 and water vapor in air.[5,6]

\[ W_T = 0.6c_a(1 - c_i/c_a)/(e_i - e_a) \quad (3) \]

Eq. 3 indicates two main avenues for improving W_T. One is to reduce (e_i - e_a), the driving gradient for transpiration. The other is to reduce c_i (c_a being assumed constant) to increase the gradient of CO_2 concentration.[1,5]

**Changing the Driving Gradient for Transpiration**

The most effective way to improve crop W_T is to achieve a larger proportion of crop growth when evaporative demand is low.[1-4] i.e., when e_a is high relative to e_i. Choosing an appropriate crop or variety for the location and sowing the crop at the recommended time are vital management activities. Crop or variety choice can be expanded by breeding to adjust sowing time and crop phenology. Eliminating disease susceptibility may present additional breeding opportunities to adjust sowing time and phenology. Promoting greater early leaf area growth in temperate cereals increases transpiration when evaporative demand is low.

Leaf temperature determines the value of e_i, so traits that reduce leaf temperature will help to reduce e_i. Evaporative demand is usually greatest during the second half of the day. Diurnal changes in stomatal conductance, leaf rolling, and other leaf movements may reduce water loss, although they are also likely to reduce carbon gain.

**Changing the Leaf Internal CO_2 Concentration**

In theory, large gains in W_T are possible for relatively modest changes in c_i.[5] According to Eq. 3, changing c_i/c_a from 0.7 (a typical value for nonstressed plants of C_3 species) to 0.6 should result in a gain of 33% in W_T, recalling that W_T is a function of (1 - c_i/c_a). Measuring genotypic differences in c_i/c_a is tedious. Thus, any rapid, indirect measure of variation in c_i/c_a has great appeal. Carbon isotope discrimination provides such a measure.[5,6]

**Carbon Isotope Discrimination**

Carbon isotope discrimination (\(\Delta^{13}C\)) is a measure of the ratio of the stable isotopes of carbon (\(^{13}C/^{12}C\)) in plant material relative to the value of the same ratio in the atmosphere.[6] Approximately 1% of atmospheric CO_2 contains \(^{13}C\). Plants of C_3 species contain fractionally less than this, primarily because of discrimination against \(^{13}C\) during two processes: firstly, during diffusion of CO_2 into the leaf through the stomata and, secondly, during the first key step in CO_2 fixation by C_3 plants, catalyzed by the enzyme Rubisco (ribulose-1,5-bisphosphate carboxylase).[5]

Theory and experimental data indicate that discrimination against \(^{13}C\) is proportional to c_i/c_a (Eq. 4).

\[ \Delta^{13}C = 4.4 + 22.6c_i/c_a \quad (4) \]

Eq. 4 indicates that \(\Delta^{13}C\) and c_i/c_a are positively related, whereas Eq. 3 indicates a negative relationship between W_T and c_i/c_a. Thus, \(\Delta^{13}C\) and W_T should be negatively related.[5,6] This negative relationship has been confirmed in numerous glasshouse studies with genotypes of several C_3 crop species.[6,7] Genetic variation in \(\Delta^{13}C\) is substantial in all C_3 crop species tested. It is likely that \(\Delta^{13}C\) is under the control of many genes[7,9] because low \(\Delta^{13}C\)
(high $W_T$) may result from low stomatal conductance and/or high photosynthetic capacity. Nonetheless, the heritability of $\Delta^{13}C$ has often been found to be high.

**Relationships Between Yield and Carbon Isotope Discrimination**

Despite the apparent utility of $\Delta^{13}C$, complications have arisen in scaling up from the leaf and plant to W and yield in field stands.\(^{[7–10]}\) There have been few examples where low $\Delta^{13}C$ has been associated with higher yield.\(^{[8,10]}\) Examples with cereals have been studies conducted in environments where rainfall is very seasonal, crops were sown after this rainfall, and crop transpiration has dominated total crop water use. For one species, peanut, field studies consistently show greater biomass production to be associated with higher $W_T$.\(^{[7]}\) Positive relationships between yield and $\Delta^{13}C$ have been observed in many instances with cereals and other species, contrary to expectations from the negative relationship between $W_T$ and $\Delta^{13}C$ found in the glasshouse.\(^{[7,8,10]}\) Many of these studies have been with temperate cereals in environments where water supply was not a major limitation to growth or in relatively favorable Mediterranean-type environments with substantial rainfall in the pre-anthesis phase.

Several factors could account for the dominance of positive relationships between yield and $\Delta^{13}C$. Low $\Delta^{13}C$ tends to be associated with slower growth rate in the absence of water stress (not the case in peanut). Slow growth rate might be expected if low $\Delta^{13}C$ is associated with low stomatal conductance. Faster crop growth rate associated with high $\Delta^{13}C$ may give a yield advantage if soil water is replenished by rainfall or irrigation or if greater transpiration is compensated by less soil evaporation.\(^{[3,9]}\) Low $\Delta^{13}C$ tends to be associated with lower harvest index and later flowering.\(^{[8,10]}\) A recent study with wheat has shown that many of these associations may be overcome by using back-crossing to transfer low $\Delta^{13}C$ into high-yielding backgrounds.\(^{[10]}\)

**CONCLUSION**

**Maximizing Transpiration**

Vigorous early growth to reduce evaporation from the soil surface in favor of transpiration should be targeted in environments where the soil surface is frequently rewetted. Vigorous early growth may risk exhausting soil water reserves too rapidly. Combining earlier flowering with vigorous early growth may help reduce this risk.\(^{[4]}\) An alternative strategy may be to combine faster early growth with higher $W_T$ (low $\Delta^{13}C$),\(^{[10]}\) but achieving the combination may be difficult in practice.

**Exploiting Variation in Transpiration Efficiency**

Environment and species combinations should be identified for which changes in crop phenology can be made that maximize growth under conditions of low evaporative demand. Promoting vigorous growth at low evaporative demand through effective crop management and targeted breeding will also prove useful, provided consequent risks are minimized.

**Exploiting Variation in Carbon Isotope Discrimination**

If $\Delta^{13}C$ is to be used for improving crop $W_T$, it is likely to have ready application in dry environments where transpiration accounts for a large proportion of crop water use.\(^{[8,10]}\) Low $\Delta^{13}C$ is unlikely to be important in environments where a large proportion of water is evaporated from the soil surface unless it can be combined with faster early leaf area growth (see “Maximizing Transpiration”). More consistent yield advances from selecting for low $\Delta^{13}C$ may be made by identifying those species or genotypes of species in which the association between $\Delta^{13}C$ and crop growth rate is positive, as in peanut. Conversely, it is possible that selection for high $\Delta^{13}C$ may be useful to maximize assimilation rate of C₃ crop species grown in irrigated or moist environments, or if selection for high $\Delta^{13}C$ results in faster canopy growth in short-season environments or where evaporation from the soil surface is substantial.

Wax Esters from Transgenic Plants

Kathryn D. Lardizabal
Monsanto, Calgene Campus, Davis, California, U.S.A.

INTRODUCTION

Wax esters are long-chain linear esters of fatty acids and fatty alcohols. They are commonly found as a component of the cuticle that covers plant surfaces where they help provide protection against stresses such as desiccation, wetting, and pathogen attack. A small number of plants produce and store wax esters in the seed instead of the more commonly found triacylglycerols. These seed storage lipids provide energy for use during germination. Of these plants, jojoba (Simmondsia chinensis) is the only one that is commercially cultivated; however, the economics involved in the growth and harvesting of this crop have limited the use of jojoba oil as an industrial feedstock. With the advent of biotechnology, the opportunity arose to overcome this limitation and produce wax esters in a temperate crop, such as Brassica napus, which is grown on far greater acreage with more favorable economics. The genes involved in the production of wax esters in jojoba were cloned and introduced into Brassica napus in order to produce wax esters transgenically.

WAX BIOSYNTHESIS IN JOJOBA

Jojoba (Simmondsia chinensis) produces long-chain wax esters exclusively as a seed storage lipid rather than triacylglycerols. A cross section of developing jojoba embryos reveals the presence of lipid bodies analogous to those present in all oilseeds. Two proteins are responsible for this biosynthesis. A fatty acyl-CoA reductase (FAR) carries out the four-electron reduction of an acyl-CoA to form a primary alcohol. The enzyme requires NADPH as the electron donor and prefers very-long-chain (C20–C24) fatty acyl-CoA substrates. This preference is reflected in the wax composition of jojoba, where greater than 93% of the fatty acids are C20–C24. Though the reaction proceeds through an aldehyde intermediate, free aldehyde is not released in the process. Next, a fatty alcohol acyltransferase (wax synthase, WS) transfers a second acyl-CoA molecule to the primary alcohol to form the wax ester (Fig. 1). Since the FAR prefers very-long-chain substrates, an efficient mechanism for fatty acid elongation system is essential. The endoplasmic reticulum contains such a system, which involves four enzymatic activities; however, the first enzyme, beta-ketoacyl-CoA synthase (KCS), was found to be the rate-limiting and chain-length-determining step.

IDENTIFICATION OF THE GENES RESPONSIBLE FOR WAX BIOSYNTHESIS

The enzyme activities involved in wax production in jojoba were described in the late 1970s; however, the membrane-associated nature of the proteins hindered their identification for another 20 years. Following cell fractionation of developing jojoba embryos, the activities are found in both the membrane and floating wax fractions. Purification of the proteins was achieved by detergent solubilization of the activities and chromatographic separation of the proteins followed by peptide sequencing and cloning of the corresponding genes.

The jojoba FAR was identified as a 1.7 kb gene that encoded a protein with a molecular mass of 56.2 kD and a pI of 8.76. Hydropathy analysis suggested the presence of 1–2 transmembrane domains. Expression of the protein in E. coli resulted in the production of a small amount of primary alcohol in the cells. The jojoba FAR was expressed in Brassica napus in combination with the KCS from Lunaria annua, in order to maximize the substrate available to the enzyme. Low levels of alcohol were detected to about 6%. Further investigation, using nuclear magnetic resonance spectroscopy and GC/mass spectrometry, showed that a majority of the alcohols were esterified to fatty acids, though the presence of unesterified alcohol indicated the incorporation into wax was incomplete. This confirmed the ability of the jojoba FAR to produce esters transgenically in another plant and also identified the presence of an endogenous wax-esterifying activity in Brassica napus.

The jojoba WS was also purified from membrane fractions. This enzyme proved to be more versatile, demonstrating activity toward a wide range of acyl-CoA and alcohol (C8–C24; saturated; monounsaturated and polyunsaturated) substrates in in vitro assays. It was also more difficult to purify due to its inhibition by detergents.
and a requirement for phospholipid reconstitution in order to restore enzymatic function. The jojoba WS was identified as a 1.3 kb gene that encoded a protein with a molecular mass of 40.2 kD and a pI of 9.86. Hydropathy analysis suggested the presence of 7–9 transmembrane domains. The jojoba WS was cloned and expressed in the model oilseed plant *Arabidopsis thaliana* in combination with jojoba FAR and *Lunaria* KCS. All three genes were under the control of napin regulatory sequences that directed gene expression to the seed and coordinated the timing of expression to coincide with fatty acid deposition during embryo development. Intact wax levels were determined on seed pools using $^{13}$C-NMR. The highest expressing plants stored approximately half of their lipid in the form of wax. Further analysis showed that up to 68% wax was produced in individual seeds.$^{[10]}$

**PRODUCTION OF WAX ESTERS IN Brassica napus**

Identification of the genes involved in wax production provided the tools necessary to produce wax esters transgenically in a commercial crop. The three-gene construct (jojoba WS; jojoba FAR; *Lunaria* KCS) was transformed into *Brassica napus* var. Reston, and a range of wax levels (0.2–14%) was detected in the transgenic R1 seed pools (Table 1). Single seed analysis of the highest

Fig. 1 Wax biosynthetic pathway in jojoba.

![Wax biosynthetic pathway in jojoba](image)

Fig. 2 The weight percent of very-long-chain (VLC) fatty acids and alcohols of individual half-seeds of transgenic *Brassica* determined by GC analysis is plotted against the estimated weight percent wax determined by GC analysis. Data from the first (R1) generation of seed (8559-13) and data from the second (R2) generation of seed (8559-13-9).
wax-containing lines indicated that up to 33% wax ester and 68% very-long-chain-fatty-acids (VLCFA) were made. Selected lines were advanced to the next generation (R2) where wax ester content increased to 64% and VLCFA content increased to 75%. It is important to note that wax and VLCFA levels for a given population represent an average of the single seed content. In R2 seed, wax levels range from 28–64% with an average of 49%, and VLCFA levels range from 64–75% with an average of 70% (Fig. 2).

CONCLUSION

Overexpression of wax biosynthetic genes (WS, FAR, KCS) in the seeds of Brassica napus resulted in the storage of approximately 50% of the lipid as wax ester. In jojoba, these genes contribute to the high levels of wax esters (50–60% by weight of the seed) found there. The proteins encoded by these genes clearly are optimized for this production since wax esters represent the entire stored form of lipid in jojoba seeds. Since acyl-CoAs are the substrates for both wax ester biosynthesis and triacylglycerol biosynthesis, the achievement of a 50% diversion of substrate, in developing Brassica seeds, into a novel storage product (wax ester) indicates that the wax biosynthetic enzymes compete efficiently for these substrates. The stored wax ester also appears to be stable and nontoxic to Brassica embryos since the seeds can be propagated.

The capacity to produce wax esters resides in the genetic makeup of nearly all plants since they are found as a component of the cuticle. In Brassica, expression of the jojoba FAR in combination with the Lunaria KCS produced a limited amount of wax ester in the absence of jojoba WS. A similar observation was made in Arabidopsis. The source of this wax-ester-forming activity was presumed to come from one or more of the seven genes identified in Arabidopsis that share homology to jojoba WS, an indication that these genes are present in Brassica and, most likely, other plant species.

Many waxes found in nature are used in the lubricant, food, and cosmetic industries. In particular, jojoba oil is used in cosmetics because of its moisturizing ability, despite its high cost. By demonstrating the production of high levels of wax esters in transgenic Brassica, the possibility for commercial production of wax esters in a temperate crop has become reality.

Weed Management in Less Developed Countries

Peter R. Hobbs
Robin R. Bellinder
Cornell University, Ithaca, New York, U.S.A.

INTRODUCTION

Weeds cause yield losses in both developed and less developed countries (LDCs). The difference between the two groups of countries lies in the degree of technology available to and utilized by farmers. The primary method of controlling weeds in LDCs continues to be hand weeding. Although farmers utilize crop rotations, intercropping, and mulches to suppress weeds, their wives and children, hired laborers, and the farmers themselves continue to hand-weed crops of significant economic value. With the increasing influence of satellite TV, youth in LDCs are becoming disenchanted with the drudgery of farming and are leaving the villages for jobs in urban centers. The cost of hand weeding is escalating and becoming too expensive. LDC farmers are interested in exploring the use of new tillage and mechanical weeding tools, planting strategies, herbicides, and genetically modified crops.

WEED LOSSES

Crop yield losses due to weeds are difficult to estimate because of interactions with insects, diseases, soils, crops, and the environment. Nevertheless, a 10% yield loss is accepted as a global figure. Pathak et al. calculated that yield losses in transplanted rice range from 10–50%, and from 50–90% in upland rice.

TRADITIONAL WEEDING STRATEGIES

Since the beginning of agriculture, the major weed-control strategy has been hand weeding, and the same is still true today in most LDCs. Farmers employ family members or hired labor using an array of hand tools that have been developed for local conditions, crops, and weeds present. There are differences in weed control strategies between larger commercial farms and smaller farm households in LDCs. In subsistence situations, farmers rely on family labor for weeding and often use weeds for animal fodder or even as human food. Commercial farmers with larger land holdings use more hired labor and herbicides, because with them weed control is easier and less costly. LDC farmers, subsistence and commercial, do understand the need for integrated weed control and use crop rotations, mulches, stale seedbed systems, water, and in some cases herbicides to control weeds.

Although hand weeding is a traditional system, it is also tedious, grueling, and often done by resource-poor labor, especially women and children. In a way, it perpetuates poverty because the employment opportunities it provides hardly compensate for the labor and the long hours in the field. Crops that receive the highest priority for hand weeding in LDCs are high-value vegetables, paddy rice, and row crops like maize, cotton, and sugarcane. Estimates of time and cost for hand weeding vary depending on weed populations present, when the crop is grown (wet or dry season), and labor availability. Average figures for rice are 30–40 labor-days per hectare, with more for maize and less for wheat. Labor rates also vary with country but are usually below one U.S. dollar per day. It is estimated that one-third to one-half of the labor in rice production is for weed control. With young male labor migrating to cities in search of less tedious and better paying jobs, labor rates for weeding are increasing, making this method of weed control less and less profitable. This same phenomenon happened in developed countries at the time of the Industrial Revolution.

INTEGRATED WEED-CONTROL SYSTEMS

In many LDCs, especially in the tropics, slash-and-burn agriculture is still practiced. As soil fertility declines and weeds increase, farmers abandon land and let it rejuvenate while they move to new, reclaimed land. As agriculture becomes less mobile and farming concentrates on the same piece of land, integrated weed-control systems are needed. In situations where the same crop is grown repeatedly, weeds specific to that system will start to predominate and require control. In the rice–wheat areas of South Asia, where continuous cereal production is practiced, the grassy weed *Phalaris minor* has proliferated and created problems for control, including development of resistance to herbicides. Farmers are aware of this problem, and as hand-weeding labor becomes more
costly, many decide to change crops, introducing ones that will better compete with existing weeds. An example of this change is using sugarcane in the rice–wheat rotation in South Asia. Similarly, use of a fodder crop that is cut multiple times can help keep weeds under control. Sieving is another tool for weed control because it effectively separates weed and crop seeds (Fig. 2).

Tillage is another practice designed to control weeds. Using a stale seedbed approach, the first flushes of weeds germinate, and are then plowed down before planting the crop. However, tillage also brings more seed to the surface, enabling germination simultaneously with the crop. There is a movement to introduce new systems that reduce tillage in LDCs\(^5\) which will require innovative integrated weed management strategies. However, it has been shown that when zero-till wheat follows paddy rice, fewer weeds germinate than in conventional tillage.\(^6\) Mechanical weeding also can be introduced to control weeds after germination if crops are line-sown in straight rows. In some LDCs where crop or farm residues are available, farmers use mulch to suppress weeds. However, crop residues are valuable for animal feed, cooking fuel, or thatching and may not be available for weed-control. Selection of competitive varieties is another integrated weed control factor.

Rice is a major crop in LDCs, and there are many ways to grow rice. When it is grown under upland conditions like other cereal crops, weeds are a major problem and cause low yields. Tillage is commonly combined with hand weeding to control weeds in dryland rice. Competitive rice varieties are also favored since they are less affected by weeds. However, most rice in LDCs is grown under lowland conditions, where seedlings are raised in separate beds, uprooted, and then transplanted into soils that have been puddled (plowed when wet). Puddling restricts water percolation so that water can be ponded more easily in the field, and standing water is then used to control weeds. However, new weeds appear under this

---

**Fig. 2** Sieving and mechanical weeding in developing countries: (A) Sieving out weed seed, (B) Rotary weeder in use, (C) Rotary weeders on display. (View this art in color at www.dekker.com.)
system and will need to be controlled as weed populations shift. Some farmers plant rice seedlings in rows so that mechanical weeding can be done between rows, using simple, locally manufactured rotary weeder (Fig. 2). Additionally, most rice growers in LDCs will hand-weed the crop at least once, and many do so twice, with 30–40 workdays per hectare commonly needed for weeding. This labor-intensive job is often done by female workers and children.

HERBICIDE USE IN LDCs

Herbicides are also used in LDCs to complement other weed control measures. Use of low-dose herbicides followed by hand weeding can be very effective and less costly than using only hand weeding. Herbicides are used quite extensively in LDCs for transplanted, puddled rice. These are frequently granular formulations that are mixed with soil or sand and spread by hand. Isoproturon (for wheat in South Asia) and butachlor (for rice) are both mixed and applied this way. In many instances herbicide efficacy is variable, and in some cases poor, because of the lack of proper spray equipment and poor knowledge of proper herbicide application methods, with non-uniform distribution as a result. Many farmers apply herbicides the same way they apply insecticides and other plant protection chemicals—with single nozzle booms (Fig. 3). Spray coverage is poor, with many missed plants. What is urgently needed is instruction in how to apply herbicides. Farmers need training in the use of proper nozzle tips, multiple nozzle booms[7] that can be made locally (Fig. 3), and pressure regulators that will improve application uniformity and accuracy. Safety issues and health hazards also need to be part of the training program for farmers and applicators.

GM CROP USE

Herbicide-resistant GM crops (maize, rice, canola, wheat, and sunflower) are not presently grown in LDCs, although interest among farmers is high. Farmers want to reduce the drudgery of farming, including weeding. Governments are wary of the implications that growing GM crops might have for their export markets and so are waiting to see how global markets adapt to these crops. Several LDCs, such as China and India, have invested heavily in research so they are ready with GM crops when acceptance is assured. These crops would be a boon to farmers in LDCs because they would enable farmers to overcome one of the most arduous tasks in farming, that of hand weeding. Direct-seeded rice would be much more feasible and would mean that rice farmers would not have to degrade their lands through puddling, which would contribute to more environmentally sustainable production systems over time.

CONCLUSION

Farmers in LDCs, like farmers in any country, are aware of the losses in yield from weeds. They have traditionally used hand weeding as the major means to control them, but as costs for labor increase and young laborers shun the drudgery of agriculture, alternative integrated systems—including the use of herbicides and herbicide-resistant crops—will be welcomed by LDC farmers, just as they are by commercial farmers in developed countries.

Weed Management in Organic Cropping Systems

Ilse A. Rasmussen
Danish Institute of Agricultural Sciences, Slagelse, Denmark

INTRODUCTION

The aim of this review is to provide an overview of weed control methods available for organic farming systems based on research mainly from Europe and North America, but measures mentioned here are not necessarily allowed in organic farming. Biological control of weeds is not considered in this review.

BACKGROUND

Synthetic herbicides are not allowed in organic farming systems. Therefore weed management relies on a combination of preventive measures and direct control to prevent severe yield losses because of weeds. Because the obtainable efficacy of each preventive or direct weed control method is lower than in conventional weed management systems, weed management measures must be combined and planned, not only for the current crop but for a number of years covering the whole crop rotation system. The crop rotation system is primarily determined by choice of crops, which is in turn determined by, first, the type of farm (feed production for animals, cash crops, horticultural crops, etc.) and, second, by the level of weed infestation in the fields.

PREVENTIVE METHODS

Preventive as well as direct control measures can be used at many points in the cropping cycle and thus affect weed population dynamics at different growth stages (Fig. 1). The main target for each measure is listed in Table 1. However, impact on any one phase will influence the next or all the following phases (e.g., increased crop competitiveness will decrease weed biomass, which will in turn reduce weed propagation, resulting in a reduction of new propagation structures into the soil and, consequently, reduction of weed infestations in succeeding crops). Different preventive weed control strategies are currently available and will be described in the following sections.

Increasing Crop Competitiveness

Crops and weeds compete for light, water, and nutrients. The farmer can assist the crop in competition by a range of measures. In cereals, varieties with a taller canopy, faster growth rate, or denser canopy may reduce weed biomass by as much as 25%. Attributes such as early and deep rooting pattern, early vigor, larger leaf size, and allelopathic ability further increase cultivar competitiveness. Giving crops, rather than weeds, better access to nutrients augments crop competitiveness. Because most annual weeds germinate from the top few centimeters of the soil, nutrients broadcast on the top of the soil, or worked into the top 5 cm, will give the weeds equal opportunity to utilize these nutrients together with the crop. Nutrients placed with precision in relation to the crop seed can be utilized by the germinating crop earlier and more efficiently than by the weeds, resulting in up to 50% reduction in weed biomass. Higher crop density results in better competitiveness of the crop. Crops planted in rows allow for weeds to utilize the light between the rows, whereas crops that are uniformly distributed are better at competing with the weeds, resulting in a 30% decrease in weed biomass. Crop plants that emerge earlier than weed plants have an advantage in competition, whereas the opposite is the case if the weed emerges first. The seedbed or planting bed should be made for the best establishment of the specific crop and crop seeds, which have high vigor and germination capacity, should be used. Growing different crops such as cereals and pulses together can augment crop competitiveness, although weed suppression alone is unlikely to justify this strategy.

Reducing Numbers of Weed Propagation Structures

The density of weeds found in a crop is proportional to the density of weed propagation structures present in the soil. The density can be decreased by reducing input, which can be attained by controlling the weeds through added competition or mortality before they mature. A second option is to remove or destroy reproductive structures by harvesting the crop before the maturity of the weed seeds

+=main target; (+)=minor target; *=secondary effect on other targets.
leaves weeds growing within crop rows unaffected. Flaming can be used to kill weeds that emerged earlier than the crop in crop rows or in heat-tolerant crops.\[2] Implements that work very close to the crop plants in the rows are being developed, such as finger weeder and torsion weeder. Hand weeding, hand hoeing, and rouging are still important methods in high-value row crops. In broadcast crops, control can be carried out by a spring-tine harrow. If the crop plants are larger than the weeds, the weeds will be damaged more by the harrow.\[13] Crops have different sensitivities to disturbance; monocots such as cereals are less sensitive than dicots, and high crop density in the rows causes the tines to move away from the rows, thereby making the control selective.\[13]

**Uncropped Soil**

When there are no crops, such as after harvest or before sowing, there is ample opportunity to carry out direct weed control, as there is no crop that can be damaged. This is used in a false seedbed, where a seedbed is prepared 1–2 weeks prior to sowing, and germinating weeds are killed before the actual sowing of the crop,\[2] in fallow, where a cropping season, or part of one, is used for intensive cultivation against perennials as well as annuals,\[2] and in stubble cultivation and tillage against perennial weeds, including plowing.\[2]

**CONCLUSION**

Weed management in organic farming systems is based on a combination of preventive and direct control measures, and the success of weed control depends on this combination. Future prospects include better understanding of weed population dynamics, so that the long-term effects of different weed management strategies can be predicted and new methods for more precise direct weed control can be developed.

INTRODUCTION

Weeds are the primary pest problem in most turf areas, particularly in lawns. Cultural management including mowing, fertility, and irrigation, along with site and turfgrass species selection, can be used to minimize most weed problems. Herbicides are used for both pre- and postemergence weed control although relatively few active ingredients are available compared to compounds used in conventional agriculture.

IMPORTANCE OF TURF

Turf is a contiguous community of plants, usually grasses, that can withstand routine defoliation (mowing) and traffic. Turf acreage is increasing in the United States, with approximately two-thirds in home lawns. No reliable figures exist for determining the value of turf but the industry is actively growing and annual management inputs are at least $20 to $30 billion. In 1999, turf maintenance costs for Wisconsin’s 486,000 hectares (ha) were 1.9 billion. The social and environmental benefits of turf include green space for relaxation and recreation, reduction of stormwater runoff and groundwater recharge, pollutant absorption, dust and erosion control, and oxygen production (Fig. 1).

WEED CONCERNS IN TURF

Unlike agronomic crops, turf is grown for quality, not yield. Thus, weed tolerances are typically low and an aesthetic rather than an economic threshold is used for justifying weed control measures. Weeds are the major pest in lawn areas but on golf courses are less important than diseases. Weeds may pose health hazards directly, as in poison ivy or sandburs when in flower, and indirectly through poor traction on athletic fields or as allergens when in flower.

TYPES OF WEEDS

Most turf weeds are herbaceous, low-growing plants, because mowing prevents high-growing weeds. Turf weeds include both dicots (broadleaves) and monocots (grasses and sedges). Most are perennials, although a few annuals such as annual bluegrass (Poa annua L.) and crabgrass (Digitaria spp.) are ubiquitous and survive in many well-managed turfs. Desirable turfgrasses may be considered weeds when they occur in swards of a different species.

WEED MANAGEMENT

The purpose of a turf dictates weed acceptance levels. A highway median has up to 100% weed tolerance, whereas a golf course putting green has near zero weed tolerance.

Cultural Management

Many weeds can be avoided by using certified, weed-free seed and mulch for establishment. Imported topsoil may contain weed propagules such as quackgrass (Elytria repens L.) rhizomes and seeds. The establishment period allows many types of weeds to develop and may cause the seeding to fail because weed seeds germinate and establish faster than most turfgrasses. Weed problems are minimized by planting cool season grasses in late summer/early fall and warm season grasses in spring. Weeds often can be avoided for years if a good quality sod is used for establishment.

The key to weed management is to grow a thick, dense turf. Good mowing and fertility practices will reduce up to 90% of potential weed problems, especially if irrigation is supplied. Mowing stimulates hormones that encourage tillering and leaf growth. Each turf species has an optimal mowing height range to achieve vigorous growth and high turf density. Mowers should be set so that no more than one-third of the leaf tissue is removed at any one mowing to prevent scalping. Scalping opens the canopy for weed seed germination or development of new plants from existing vegetative propagules of weeds (e.g., rhizomes and stolons). Nitrogen (N) is almost always the limiting element for turf growth. High-quality turf requires 96–192 kg N per ha, applied incrementally during the growing season to achieve balanced turf growth with high density. This is approximately 1/7 to 1/4 of the N required for maximum growth. Potable water is best for irrigation to
avoid salts that may desiccate the turf. On average, turf uses about 2.5 cm water weekly through irrigation, precipitation, or soil moisture withdrawal.

Weed identification is used to select appropriate chemical controls and to diagnose underlying problems that may be corrected to prevent future weed development.[4]

Crabgrass infestation is often due to scalping in the spring. Quackgrass, ground ivy (*Glechoma hederacea*), and other weeds invade dry soil whereas many sedges prefer moist soils. Prostrate knotweed (*Polygonum aviculare* L.) indicates soil compaction, red sorrel (*Rumex acetosella* L.) indicates acidic soil, and legumes such as white clover (*Trifolium repens* L.) indicate N-deficient soil.

### Biological Controls

Few if any practical biocontrol options for turf weeds exist. A bacterial wilt disease caused by *Xanthomonas campestris* showed promising results in laboratory tests but was relatively ineffective in field trials.[5] Corn gluten meal offers promise as a preemergent herbicide but in current form the effects are ephemeral, timing and moisture are crucial, and high rates may be required.[6]

### Chemical Controls

The types and classifications of chemical controls are similar to those used in agronomic crops (Table 1); however, fewer active ingredients are available because manufacturers typically have little financial incentive to support labels for what is essentially a minor use. Homeowners have access to most of the active ingredients available to professionals, although concentrations and formulations may differ. Preemergent herbicides are used to prevent establishment of new weeds (primarily annuals) from seed. Most weed control is performed postemergent, particularly for perennial broadleaf weeds. Relatively few contact herbicides are used because most problem weeds are perennials that require a systemic herbicide. Liquid products often are more effective than granules, although granules are often perceived as being safer for use. Many granular products are formulated as a combination of fertilizer and herbicide for either pre- or postemergent weed control.

A common perception exists that turf requires a large amount of pesticides, especially herbicides, although in fact herbicides often are used in lieu of proper cultural management practices that could reduce the need for herbicides. Golf course purchase of herbicides for 1995/96 was just over $60 million, whereas $130 million was spent on professional lawn care.[7] Data on product purchases by homeowners are unavailable, but likely meet or exceed that used by professional lawn care because only about half of the 22% of home lawns treated with pesticides utilize a professional service.[7] Adoption of integrated pest management practices has led to many of the postemergent liquid herbicide applications used as spot treatments to individual weeds or patches rather than broadcast applications.

Another common perception is that herbicides are readily leached or lost in runoff from turf surfaces. Data from multiple research projects since the 1980s indicates that relatively little herbicide applied to dense turf

</table>
(<1%) is capable of leaching to groundwater.\[8\] Runoff losses may be potentially higher, although less than 15% of water soluble herbicides applied to short-cut golf course fairways are likely to run off, even under worst-case scenarios.\[8\] Higher mowing heights and thatch further reduce leaching and runoff due to higher runoff resistance and the pesticide-binding capacity of organic matter in the turf.\[3,9,10\] Mowed turfgrasses provide a dense turf cover of 75 million to >20 billion shoots per hectare. Kentucky bluegrass (\textit{Poa pratensis} L.), commonly used for lawns, can have up to 16,000 kg per hectare of root biomass.\[3\] Soil type, soil saturation, timing of precipitation or irrigation following application, application rate, water solubility, and adsorption to organic matter can substantially affect the amount of herbicide in leachate or runoff.

\section*{THE FUTURE}

A few lawn care companies have programs to meet the small but growing demand for organic lawn care. No legal definition of organic lawn care exists. Consequently, organic lawn care relies on naturally occurring fertilizers (e.g., composted sewage sludge or manure) and avoids synthetic chemicals. Because increased pesticide restrictions are limiting the development of new synthetic chemicals, the development of natural products for weed control is expected to grow.

\section*{CONCLUSION}

Turf acreage is expanding as the population grows and turf maintenance has a tremendous economic impact in urbanized states. Weeds are usually the greatest pest problem in turf. Most weed problems can be managed using practices that develop a thick turf sward. Herbicides are used for weed control in all types of turf in either liquid or granular products, sometimes in combination with fertilizer.

Wheat Rusts

James A. Kolmer
United States Department of Agriculture—Agricultural Research Service and
University of Minnesota, St. Paul, Minnesota, U.S.A.

INTRODUCTION

The rusts of wheat (Triticum aestivum L.) are among the most common and important diseases of wheat on a worldwide basis. Wheat stem rust is caused by Puccinia graminis f. sp. tritici, leaf rust is caused by Puccinia triticina, and stripe rust is caused by Puccinia striiformis f. sp. tritici. When wheat cultivars are fully susceptible and the weather is ideal for repeated cycles of rust infection, wheat rusts can cause severe loss of yield, sometimes destroying whole fields of wheat. The three wheat rusts are genetically diverse, consisting of many different pathogenic races. Widespread use of wheat cultivars with specific rust resistance genes selects races of wheat rusts that have virulence to the resistance genes, resulting in rapid changes in rust races. Wheat cultivars that are resistant when initially released can lose their resistance because of the selection of these virulent rust races. Sources of partial resistance to the wheat rusts that appear to be race non-specific are available and offer long-lasting, economical control of these important diseases.

WHEAT RUST LIFE CYCLE

The rust diseases of wheat are spread over large geographical areas by means of air-borne urediniospores (Fig. 1). Urediniospores are pigmented, dikaryotic (have two haploid nuclei, n+n), and are the epidemic stage of the disease on wheat. Urediniospores germinate and infect wheat plants when temperatures are mild, and the leaves and stems are wet with dew or rain. The urediniospores produce specialized infection structures (apressoria, germ tube, and penetration peg) that enable the spores to penetrate the host plant stomata. After formation of a substomatal vesicle, specialized haustoria are formed, which are used to obtain nutrients from within mesophyll cells without killing them. Infectious hyphae of the fungus spread throughout the mesophyll tissue layer, resulting in the formation of additional haustoria. Rust infections on wheat leaves become visible as faint flecks within 3–4 days after the initial infection. By 8–10 days following infection, dark sporulating pustules called uredinia (Fig. 1) erupt and break through the epidermis of the wheat plant. Each uredinium can produce from 3000 to 10,000 urediniospores per day. Freshly produced urediniospores are carried by wind to new sites on the same plant or to different plants, where each new spore has the potential to infect the host plant. The explosive nature of rust epidemics results from the exponential increase in uredinial infections in the early stages of the epidemic. As the uredinia age, teliospores are formed among the urediniospores in the uredinia. Eventually, only teliospores are formed in the uredinia. Teliospores are dark, thick-walled, and have two cells. Each cell in the teliospore is initially dikaryotic (n+n). Later in development, the nuclei fuse to form a diploid (2n) nucleus, which undergoes meiosis as the teliospore germinates. The teliospores are resting structures, which are used for overwintering, as in the case of P. graminis, or for oversummering, as in the case of P. triticina. The teliospores survive the winter or summer on wheat straw stubble, and germinate the following spring or fall. Each cell of the teliospore can produce a curved, four-celled promycelium, which produces four haploid (n) basidiospores. The basidiospores are clear and hyaline. Basidiospores are ejected from the promycelium and carried to short distances by wind to infect the alternate host. Because basidiospores are incapable of infecting wheat plants, alternate hosts must be present in the local vicinity for the wheat rusts to complete the sexual cycle. In North America, the three wheat rusts survive asexually in the uredinial stage by alternating between winter wheat and spring wheat or susceptible grasses because susceptible alternate hosts are usually not present. Each basidiospore infection on the alternate hosts produces haploid structures called pycnia, which appear as circular, yellow pustules on the upper leaf surface. The pycnia produce minute pycniospores and flexuous hypha that are haploid. Pycniospores are carried by insects or water to the flexuous hyphae present in other pycnia. The wheat rust fungi are heterothallic, with two different mating types. The transfer of nuclei from pycniospores to flexuous hyphae (plasmogamy) occurs with compatible combinations of mating type. After fertilization, aecia develop on the underside of the leaf beneath the pycnial infections, and eventually form clusters or cups that produce...
The aeciospores are dikaryotic and wind-dispersed and infect wheat plants in the same manner as urediniospores. Infections resulting from aeciospores give rise to the production of uredinia on the wheat plants, completing the life cycle and initiating the asexual spore stage. The origin, specificity, structure, and physiology of wheat rusts have been previously reviewed. The distribution, epidemiology, and control of the three wheat rust diseases have also been reviewed.

**WHEAT STEM RUST (P. GRAMINIS PERS.: PERS. F. SP. TRITICI ERIKSS. AND HENN.)**

Stem rust is potentially the most destructive rust of wheat. In North America, continent-wide epidemics occurred periodically from 1900 to 1954, which caused huge losses in wheat yields. In the state of Minnesota in the United States in 1953, 75% of the durum wheat crop was lost, and in the province of Manitoba in Canada, 40 million bushels of wheat were lost to stem rust. Stem rust is found mostly in regions with a continental climate where summer temperatures regularly reach 25–35°C. The optimum temperatures for infection and growth are 20°C and 30°C, respectively. Stem rust has been a major disease of wheat in North America, the southern cone of South America, continental Europe, the Indian subcontinent, Australia, and China. Although harmful at all times to wheat, stem rust has the potential to be very destructive late in the growing season. Crops within a few weeks of harvest can be devastated by infections of stem rust that prevent grain filling. Stem rust urediniospores are dark red (Fig. 2), and uredinial infections are found mostly on the stem, although uredinia can also form on the leaves and leaf sheaths. Host specificity in rust fungi was first demonstrated in stem rust. Different isolates of *P. graminis* f. sp. *tritici* derived from single urediniospores had different infection types of uredinia when tested on a set of wheat cultivars that differed for stem rust resistance genes. In North America, the alternate host, common barberry (*Berberis vulgaris* L.), was largely eradicated during the 1920s to the 1950s. Elimination of the sexual cycle has reduced the number of stem rust races present in North America. Stem rust has been successfully controlled throughout most of the world by cultivation of wheats that have high levels of resistance provided by stem rust resistance genes. Over 40 *Sr* (stem rust resistance) genes have been identified; however, many of the genes do not...
provide resistance because races with virulence to many genes are common. Wheat cultivars with Sr2 and Sr31 have been resistant worldwide because stem races with virulence to these genes have only rarely been found. Temperatures for infection and growth are 20°C and 25°C, respectively. Leaf rust urediniospores are dark brown red (Fig. 3), and the uredinia are found on leaves and leaf sheaths. The alternate hosts Thalictrum speciosissimum Loefl. and Isopyrum fumariodes L. are found in southern Europe and northeast Asia, respectively. However, almost all P. triticina populations reproduce by asexual reproduction of urediniospores because susceptible alternate hosts are usually absent. Despite the lack of a sexual cycle, P. triticina populations are highly diverse for virulence to leaf rust resistance genes in wheat. The wide range of adaptation of P. triticina, combined with the many different races that exist, has made long-lasting or durable leaf rust resistance in wheat difficult to achieve. Over 50 Lr genes in wheat have been described, but few condition effective resistance. However, wheats with resistance gene Lr34, combined with other genes, have been shown to have durable resistance to leaf rust.

WHEAT LEAF RUST (P. TRITICINA ERIKSS.)

Leaf rust is the most widely distributed and regularly occurring of the wheat rusts. In North America, leaf rust occurs annually almost wherever wheat is cultivated. Leaf rust is also a major disease of wheat in the southern cone of South America, western and central Europe, the Middle East, central Asia, and parts of the Indian subcontinent. Leaf rust can also be an important disease in Australia and China. P. triticina is also referred to as brown rust of wheat. In North America, annual losses because of leaf rust usually range from 2% to 10%. Leaf rust is most destructive in climates with fall and winter temperatures that allow the rust to infect fall-sown wheat and survive the winter as mycelial infections. Warm temperatures in the spring allow leaf rust infections to sporulate and increase while the wheat crop is breaking dormancy. This leads to heavy infections of the flag leaves before the plants have headed, resulting in severe crop loss. Leaf rust can also be severe on spring-sown wheat in regions that have summer temperatures of 20–30°C. The optimum temperatures for infection and growth are 20°C and 25°C, respectively. Leaf rust urediniospores are dark brown red (Fig. 3), and the uredinia are found on leaves and leaf sheaths. The alternate hosts Thalictrum speciosissimum Loefl. and Isopyrum fumariodes L. are found in southern Europe and northeast Asia, respectively. However, almost all P. triticina populations reproduce by asexual reproduction of urediniospores because susceptible alternate hosts are usually absent. Despite the lack of a sexual cycle, P. triticina populations are highly diverse for virulence to leaf rust resistance genes in wheat. The wide range of adaptation of P. triticina, combined with the many different races that exist, has made long-lasting or durable leaf rust resistance in wheat difficult to achieve. Over 50 Lr genes in wheat have been described, but few condition effective resistance. However, wheats with resistance gene Lr34, combined with other genes, have been shown to have durable resistance to leaf rust.

WHEAT STRIPE RUST (P. STRIIFORMIS F. SP. TRITICI WESTEND.)

Stripe rust is a major disease in wheat-growing areas of the world where temperatures remain cool and moderate during the growing season. The stripe rust fungus has optimum temperatures of 11°C and 13°C, respectively.
CONCLUSION

Wheat rusts are challenging plant pathogens. Although stem rust has been successfully controlled by resistant wheat cultivars, epidemics of leaf and stripe rust occur regularly in many different regions of the world. Development of rust-resistant wheat cultivars and research on the biology and genetics of wheat rust fungi need to continue to reduce losses to these devastating and recurrent diseases.

Yeast Two-Hybrid Technology

University of Florida, Gainesville, Florida, U.S.A.

INTRODUCTION

Over the past decade, protein–protein interactions have drawn broad attention because most cellular proteins function through association with other proteins, and the networks formed by protein complexes control most biological processes. To study protein–protein interactions, a number of technologies have been developed. Among them, the yeast two-hybrid system appears to be a relatively simple, yet powerful tool. This system has recently been used to detect interactions between thousands of protein pairs in the model organism yeast.

MECHANICS OF THE YEAST TWO-HYBRID SYSTEM

The two-hybrid system, performed within the yeast Saccharomyces cerevisiae, takes advantage of the independent domains present in many transcription factors, such as the yeast Gal4 protein. The two physically separable, functionally independent domains are a DNA-binding domain and a transcription activation domain. The DNA-binding domain targets the transcription factor to a specific promoter sequence (known as the upstream activation sequence (UAS) in yeast), whereas the activation domain recruits the transcription complex for initiation of transcription. A mutant transcription factor lacking either one of the two domains fails to activate transcription of the downstream gene driven by the promoter. The independence of the two domains was shown when early investigators revealed that a hybrid transcription factor could be reconstituted in yeast cells by fusing the Gal4 DNA-binding and the Gal4 transcription activation domains to two physically interacting proteins, respectively (Fig. 1). To demonstrate activity of the hybrid transcription factor, a reporter gene, such as the bacterial lacZ gene, driven by a promoter containing the UAS where the Gal4 DNA-binding domain interacts, was also introduced into the cells. The lacZ gene encodes the β-galactosidase enzyme that can hydrolyze the colorless substrate 5-bromo-4-chloro-3-indolyl-β-D-galactoside (known as X-gal) and generate a blue product. Thus, the formation of blue yeast colonies in medium containing X-gal is indicative of reconstitution of a functional transcription factor by the interaction of the two proteins that bring the Gal4 DNA-binding and activation domains into proximity. These studies led to the establishment of the yeast two-hybrid system.

The original yeast two-hybrid idea has been applied to screening of cDNA libraries to identify proteins (commonly called “prey”) that interact with a given protein (also called “bait”). The cDNAs are cloned into a Gal4 activation domain vector to generate translational fusions (prey) of the library proteins to the Gal4 activation domain. In addition to lacZ, a nutritional selection reporter, such as the yeast HIS3 gene, is placed under the control of a Gal4-responsive promoter. To carry out two-hybrid screening, the prey library is transformed into the his3/C0 mutant that expresses the bait protein and carries an engineered HIS3 gene driven by a Gal4-responsive promoter. The transformed cells are then selected onto medium lacking histidine. The physical association between the bait and a prey activates transcription of the HIS3 gene, allowing the transformed cells to grow and form colonies in the absence of histidine. To confirm the interaction identified by the HIS3 reporter, the selected cells can be subjected to an assay for β-galactosidase activity using the chromogenic substrate X-gal.

USING THE YEAST TWO-HYBRID SYSTEM TO DISSECT PLANT SIGNAL TRANSDUCTION PATHWAYS

Yeast two-hybrid screens have been used to identify proteins involved in plant signal transduction pathways that regulate plant defense and development. The Arabidopsis protein RPM1 confers resistance to the bacterial
pathogen *Pseudomonas syringae* expressing either of the two effectors AvrB and AvrRpm1. An Arabidopsis protein, RIN4 (for RPM1-interacting protein 4), was found from a two-hybrid screen using the bacterial protein AvrB as bait. RIN4 interacts with both AvrB and RPM1. Subsequent genetic analysis confirmed that RIN4 is required for accumulation of RPM1 and for RPM1-mediated disease resistance.

The *Arabidopsis* Brassinosteroid-Insensitive 1 (BRI1) gene encodes a receptor kinase protein that initiates the brassinosteroid signal transduction pathway. Brassinosteroids are a class of endogenous plant hormones that regulate different physiological processes during the course of plant development. A yeast two-hybrid screen for interactors of the BRI1 kinase domain identified a second receptor-like kinase protein, BAK1 (BRI1 Associated receptor Kinase 1). Further biochemical and genetic studies confirmed that BRI1 interacts with BAK1 in plants and that BRI1 and BAK1 function together in mediating brassinosteroid signaling.

**DETECTION OF PROTEIN–PROTEIN INTERACTIONS ON A GENOMEWIDE SCALE**

The most recent application of the yeast two-hybrid system is the comprehensive study of protein–protein interactions between thousands of protein pairs. The approximately 6000 predicted open reading frames from the yeast *Saccharomyces cerevisiae* were individually expressed as Gal4 DNA-binding and transcription activation domain fusions in yeast strains of opposite mating types. To screen for binding between any two yeast proteins, cells expressing the Gal4 DNA-binding fusions were systematically mated with the cells expressing the Gal4 activation fusions. Diploids from the mating were then subjected to an assay for expression of the reporter genes under the control of Gal4-responsive promoters. Using this approach, more than 4000 protein–protein interactions have been discovered. These studies are particularly important as a large number of genes have been predicted from genome sequencing projects, ranging from unicellular organisms, such as yeast, to multicellular organisms such as *Arabidopsis* and rice. The identification of protein–protein networks can link distinct biochemical pathways and facilitate the studies of unknown proteins whose binding partners have been characterized.

**CONCLUSIONS AND PROSPECTIVES**

More than 10 years have passed since the yeast two-hybrid technology was first described. Although some drawbacks, such as false–positive interactions, have been found, the system is still popular for the study of protein–protein interactions. The viability of the two-hybrid system relies on its simplicity in manipulation of libraries and sensitivity in detection of protein interactions. The only prerequisite for examining the binding of two proteins is their predicted open reading frames. Because of these features, the yeast two-hybrid system has evolved from a means to study interactions between small numbers of proteins to a powerful tool that can be used to establish a protein–protein interaction database on a genomewide scale. It is anticipated that such a global approach can be applied to investigate more complex organisms such as *Arabidopsis* and rice whose genomes have been sequenced. Information obtained from yeast two-hybrid analyses and from other sources will undoubtedly contribute to our understanding of cellular networks and to agricultural practices.
